Attempts have been made to understand the neural systems involved in the modulation of panic-like responses (Graeff, 1990, 1991, Graeff *et al.*, 1996). As with neural circuits regulating anxious states, it seems that neural systems mediating fight-or-flight responses must be involved, but that higher-order modulatory processes are likely to be involved. This is supported by the finding that priming of the amygdala or chronic disinhibition of the dorsomedial hypothalamus can result in a chronic vulnerability to panic-like responses to normally innocuous agents such as sodium lactate (Shekhar *et al.*, 1996; Sajdyk and Shekhar, 2000). Two key structures involved in mediating panic-like responses are the dorsal periaqueductal gray (DPAG), which mediates escape responses (Graeff *et al.*, 1996), and the rostroventrolateral medulla (RVLM), which controls the sympathetic motor component of cardiovascular responses (Dampney, 1994; Saper, 1995) (Figure 4).

### The dorsal periaqueductal gray as a nodal structure in mediating flight behavior

The DPAG is activated during panic- or escape-like responses, as determined using induction of immediate-early gene expression (Silveira *et al.*, 2001; Lamprea *et al.*, 2002), and is considered to be a model of panic anxiety (Graeff, 1994; Jenck *et al.*, 1995). Consistent with a key role of the DPAG in vulnerability to panic-like responses,

**Figure 4** Schematic diagram of two coronal sections from a rat brain (−8.18 and −11.60 mm Bregma) illustrating known projections of serotonergic neurons within the ‘lateral wings’ or DRVL/VLPAG region of the dorsal raphe nucleus. Serotonergic neurons within the DRVL/VLPAG region project to the DPAG where, via actions on 5-HT<sub>1A</sub> and 5-HT<sub>2</sub> receptors, serotonin evokes a decrease in the functional excitability of the DPAG and fight-or-flight or panic-like responses. Serotonergic neurons in the DRVL/VLPAG region also project to the RVLM, where, via actions on 5-HT<sub>1A</sub> receptors, serotonin evokes sympathoinhibition and hypotension. Overall, activation of DRVL serotonergic neurons would be expected to promote a more passive emotional coping strategy. Abbreviations: DPAG, dorsal periaqueductal gray; DRVL/VLPAG, dorsal raphe nucleus, ventrolateral part/ventrolateral periaqueductal gray; RVLM, rostral ventrolateral medulla. Scale bar, 500 μm.

pharmacological inhibition of the DPAG using the benzodiazepine midazolam (de Bortoli *et al.*, 2008), or the GABA<sub>A</sub> receptor agonist muscimol (de Menezes *et al.*, 2008; Bueno *et al.*, 2005), or the GABA<sub>B</sub> receptor agonist baclofen (Bueno *et al.*, 2005) impairs panic-like and escape behaviors, while electrical stimulation of the DPAG (Jenck *et al.*, 1995), pharmacological activation of the DPAG with the neuropeptide cholecystinin sulfated octapeptide (CCK-8s) (Zanoveli *et al.*, 2004), or disinhibition of the DPAG with the GABA<sub>A</sub> receptor antagonist bicuculline methiodide (Graeff *et al.*, 1986) increases escape responses.

#### ***The RVLM as a nodal structure mediating cardiovascular responses***

The RVLM is an important component of the neural mechanisms regulating blood pressure under baseline and stimulated conditions (Madden and Sved, 2003), and an important component of the descending pathway

mediating the sympathetic motor component of cardiovascular responses to stimulation of the dorsomedial hypothalamus (Horiuchi *et al.*, 2006). As such, it could play a role in dysregulation of panic-like responses that have been described following chronic disinhibition of the dorsomedial hypothalamus (Shekhar *et al.*, 1996; Johnson *et al.*, 2007).

#### **Modulation of anxiety-related circuits by serotonin**

Having described parts of the neural circuits regulating anxious states and panic-like responses, in this section we highlight how serotonin modulates anxious states via effects on the ventral hippocampus and basolateral amygdala, and modulates panic-like responses via effects on the DPAG and RVLM.

#### ***Effects of serotonin within the basolateral amygdala***

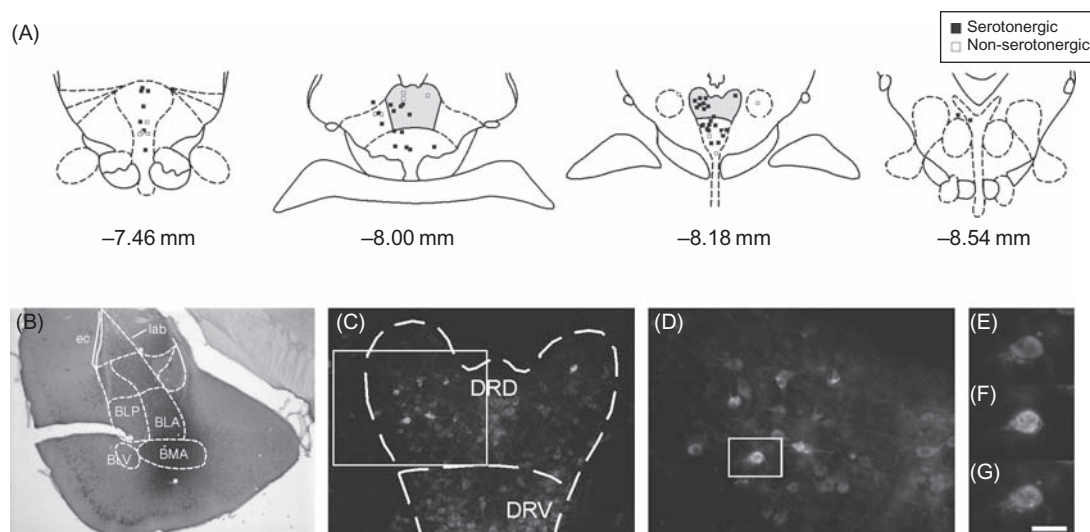

The basolateral amygdala is innervated by both serotonergic and non-serotonergic neurons within the dorsal raphe nucleus (Hale *et al.*, 2008b). Although the basolateral amygdala-projecting neurons are widely distributed across the rostrocaudal extent of the raphe complex, the highest concentrations of basolateral amygdala-projecting neurons are located in the mid-rostrocaudal region of the dorsal part of the dorsal raphe nucleus (DRD) (Ottersen, 1981; Imai *et al.*, 1986; Abrams *et al.*, 2005). We have recently reported that the majority of basolateral amygdala-projecting neurons in the midbrain raphe complex are serotonergic ( $65.2 \pm 3.0$  percent; Hale *et al.*, 2008b). However, the numbers of basolateral amygdala-projecting neurons that are serotonergic vary depending on the anatomical subdivision of the midbrain raphe complex. Fewer than half of the basolateral amygdala-projecting neurons in the ventrolateral part of the dorsal raphe nucleus (DRVL) region (both at −8.00 and −8.18 mm Bregma) were found to be serotonergic, whereas basolateral amygdala-projecting neurons in the mid-rostrocaudal DRD were mostly serotonergic ( $73.1 \pm 5.8$  percent at −8.00 mm Bregma and  $85.5 \pm 7.2$  percent at −8.18 mm Bregma; Figure 5). The neurochemical phenotype(s) of the non-serotonergic neurons projecting from the dorsal raphe nucleus to the basolateral amygdala is/are not known. The hypothesis that basolateral amygdala-projecting neurons in the dorsal raphe nucleus are involved in modulation of anxiety-related behavior is supported by the recent finding that the basolateral amygdala-projecting subset of neurons within the dorsal raphe nucleus is activated following exposure of rats to a mild anxiogenic stimulus – exposure to an

open-field under unfamiliar, low-light conditions (Hale *et al.*, 2008b).

Serotonergic neurons in the DRD region have been associated with anxiety-like responses (for review, see Lowry *et al.*, 2005). The DRD receives dense projections from anxiety-related forebrain areas, including the bed nucleus of the stria terminalis and central amygdaloid nucleus, and gives rise to projections to anxiety-related forebrain areas, including the basolateral amygdala and the ventral hippocampus (Abrams *et al.*, 2005; Hale *et al.*, 2008b; for review, see Imai *et al.*, 1986; Lowry *et al.*, 2005). Serotonergic neurons within the DRD are activated following a number of stress- and anxiety-related stimuli, including uncontrollable stress (Grahn *et al.*, 1999), social defeat (Gardner *et al.*, 2005), anxiogenic drugs (Abrams *et al.*, 2005) and anxiety-related neuropeptides (Staub *et al.*, 2005, 2006). Injection of CRF into the caudal, but not rostral, dorsal raphe nucleus induces anxiety- or fear-related behaviors measured 24 hours later in a model of learned helplessness (Hammack *et al.*, 2002); an effect that is thought to be due to an overactivation of serotonergic

neurons in the caudal dorsal raphe nucleus (Maier and Watkins, 2005). Thus, serotonergic neurons in the DRD are anatomically integrated with a distributed anxiety-related circuit, serotonergic neurons in this region are selectively activated by anxiogenic stimuli, and CRF-induced activation of this region induces behavior consistent with an increased anxious state.

Anxiogenic stimuli increase extracellular serotonin concentrations in the basolateral amygdala (Amat *et al.*, 1998a, 2004). Serotonin acting within the basolateral amygdala may have either anxiolytic or anxiogenic effects, depending on the cellular site of action and the serotonin receptor subtype involved. A role for serotonin in facilitating coping mechanisms in the amygdala is supported by findings that the overall effect of serotonin in the basolateral amygdala is a 5-HT<sub>2A</sub> receptor-mediated enhancement of GABA-mediated inhibition of projection neurons (Rainnie, 1999). In addition, recent evidence from McDonald and coworkers (Muller *et al.*, 2007) suggests that serotonergic fibers preferentially target distinct subpopulations of interneurons within the basolateral

**Figure 5** Illustrations and photomicrographs showing retrogradely labeled neurons in the dorsal raphe nucleus following injections of Cholera Toxin B-subunit (CTb) into the basolateral nucleus of the amygdala. (A) Illustrations of the distribution of basolateral amygdala-projecting serotonergic (black squares) and non-serotonergic (white squares) neurons within subdivisions of the dorsal raphe nucleus. Retrogradely labeled neurons are concentrated in the mid-rostromedial dorsal raphe nucleus (gray shaded areas at  $-8.00$  mm and  $-8.18$  mm Bregma) (Paxinos and Watson, 1998). Most but not all BL-projecting neurons in the dorsal raphe nucleus are serotonergic. (B) Photomicrograph illustrating the CTb injection site restricted to the BLA and BMA. (C) Double-labeled immunofluorescence photomicrograph showing the mid-rostromedial dorsal raphe nucleus (corresponding to  $-8.18$  mm Bregma illustration in (A)). White box in (C) indicates region shown at higher magnification in (D). White box in (D) indicates region shown at higher magnification in (E), (F) and (G). Tryptophan hydroxylase-immunoreactive (TrpOH-ir; serotonergic) neurons appear red (E), while CTb-ir (BL-projecting) neuron appears green (F). Double TrpOH/CTb immunofluorescent neuron appears yellow. Abbreviations: BLA, basolateral nucleus of the amygdala, anterior part; BLP, basolateral nucleus of the amygdala, posterior part; BLV, basolateral nucleus of the amygdala, ventral part; BMA, basomedial nucleus of the amygdala, anterior part; DRD, dorsal raphe nucleus, dorsal part; DRV, dorsal raphe nucleus, ventral part; ec, external capsule; lab, longitudinal association bundle. Scale bar:  $448\mu\text{m}$  (A);  $500\mu\text{m}$  (B);  $100\mu\text{m}$  (C);  $50\mu\text{m}$  (D),  $25\mu\text{m}$  (E, F, G). Copies produced via our print on demand service do not contain color plates; if your copy does not have the color plate, please go to this website to view the figure in color [www.elsevier.com/companions/9780123746344](http://www.elsevier.com/companions/9780123746344)

amygdala, in addition to targeting projection neurons. Thus, activation of dorsal raphe nucleus serotonergic systems would enhance inhibition in the basolateral amygdala and facilitate coping with the stressor. Significantly, activation of 5-HT<sub>2</sub> receptors in the basolateral amygdala reduces fear and anxiety in guinea pigs, as measured by a tonic immobility test (Leite-Panissi *et al.*, 2006). Imaging studies in humans support a potential role for serotonin within the amygdala in resilience (Anderson *et al.*, 2008).

Serotonin acting on presynaptic 5-HT<sub>1A</sub> receptors within the basolateral amygdala inhibits both inhibitory (Kishimoto *et al.*, 2000) and excitatory (Cheng *et al.*, 1998) transmission. As might be expected based on these electrophysiological effects, the behavioral effects of 5-HT<sub>1A</sub> receptor activation in the basolateral amygdala are complex, and appear to be dependent on the paradigm used to measure anxiety-related behavior (Zangrossi and Graeff, 1994; Gonzalez *et al.*, 1996; Zangrossi *et al.*, 1999).

In contrast to the anxiolytic or mixed effects of 5-HT<sub>2A</sub> and 5-HT<sub>1A</sub> receptor activation, respectively, in the basolateral amygdala, activation of 5-HT<sub>2C</sub> receptors appears to be anxiogenic. The cellular mechanisms are not clear, but direct injection of 5-HT<sub>2C</sub> receptor agonists into the basolateral amygdala increases anxiety-related behavior – an effect that can be reversed by 5-HT<sub>2C</sub> receptor-selective antagonists (Campbell and Merchant, 2003). Thus, pharmacological studies support a role for serotonergic systems in both facilitating and attenuating anxiety-related behavior via actions on different presynaptic and postsynaptic signaling mechanisms. It remains to be determined if these opposing effects are associated with activation of different subsets of serotonergic neurons in the dorsal raphe complex.

### ***Effects of serotonin within the ventral hippocampus/subiculum***

Like the basolateral amygdala, the vHPC is an important site for the modulatory effects of serotonin on anxious states and anxiety-related behavior. The hippocampus receives dense projections from the mid-brain raphe complex. The median raphe nucleus (MNR) sends projections predominantly to the dHPC, while the dorsal raphe nucleus sends projections predominantly to the vHPC (Azmitia and Segal, 1978; Imai *et al.*, 1986; Vertes, 1991). Consistent with this anatomical specificity, electrical stimulation of the MNR induces 5-HT release in the dHPC and the vHPC, whereas stimulation of the DR induces 5-HT release in the vHPC only (McQuade and Sharp, 1997). Ventral hippocampus-projecting neurons in the dorsal raphe nucleus are located in the caudal part of the nucleus (Imai *et al.*, 1986), a region known to contain

a population of serotonergic neurons that are sensitive to anxiogenic drugs and anxiety-related neuropeptides (Abrams *et al.*, 2005; Staub *et al.*, 2005, 2006) and anxiogenic stimuli (Grahn *et al.*, 1999; Gardner *et al.*, 2005). A subset of neurons in the caudal dorsal raphe nucleus that projects to the vHPC also projects to the basolateral amygdala (Imai *et al.*, 1986), suggesting that the dorsal raphe nucleus exerts coordinate control over multiple nodes of anxiety circuits. Similar collateral projections of serotonergic neurons in the dorsal raphe nucleus to different nodes of anxiety circuitry have been described for the prefrontal cortex and nucleus accumbens (Van Bockstaele *et al.*, 1993), hippocampus and entorhinal cortex (Kohler and Steinbusch, 1982), entorhinal cortex and septum (Kohler *et al.*, 1982), hippocampus and locus coeruleus, and locus coeruleus and amygdala (Imai *et al.*, 1986). These findings suggest that a small subset of serotonergic neurons gives rise to collateral projections to an extensive, but anatomically distributed and functionally related, anxiety circuit (Figure 1).

Serotonin release in the vHPC is increased by anxiogenic stimuli (Amat *et al.*, 1998b; Kagamiishi *et al.*, 2003). Microdialysis studies suggest an increase in serotonin release in the vHPC following exposure to the elevated plus maze (Wright *et al.*, 1992; Voigt *et al.*, 1999; Rex *et al.*, 2005) an effect that can be blocked with anxiolytic drugs such as diazepam or the 5-HT<sub>1A</sub> receptor agonist ipsapirone. It should be noted that while systemic administration of diazepam blocks the release of serotonin in the vHPC and decreases anxiety-like behavior in the elevated plus maze, ipsapirone blocks only the serotonin release, with no change in anxiety-like behavior. This may suggest a presynaptic effect of ipsapirone at the level of the dorsal raphe nucleus to inhibit serotonin release, and a postsynaptic effect, possibly in the vHPC, regulating behavior. Microinjection of the 5-HT<sub>1A</sub> receptor antagonist WAY-100635 into the vHPC reduces anxiety-related behavior in the elevated plus maze in mice naïve to the apparatus, but has no effect in mice pre-exposed to the apparatus 24 hours prior to testing. Microinjection of WAY-100635 into the dHPC was without effect on anxiety-like behavior in the elevated plus maze (Nunes-de-Souza *et al.*, 2002).

Despite the evidence for a dissociation of function of the hippocampus along its dorsal–ventral axis and the possible involvement of serotonin within the vHPC in the modulation of anxious states and anxiety-related behavior, microinjection studies with 5-HT<sub>1A</sub> agonists and antagonists, similar to studies of the basolateral amygdala, provide no clear consensus (for review, see Engin and Treit, 2007). Within the vHPC, agonists at the 5-HT<sub>1A</sub> receptor have no effect in the social interaction test (Hogg *et al.*, 1994) or elevated plus maze (File and Gonzalez, 1996), and antagonists at the 5-HT<sub>1A</sub> receptor

have been shown to have no effect in the social interaction test (Hogg *et al.*, 1994). 5-HT<sub>1A</sub> receptor antagonists have anxiolytic effects in the elevated plus maze (Nunes-de-Souza *et al.*, 2002). As in the basolateral amygdala, agonists at the 5-HT<sub>2C</sub> receptor have anxiogenic effects in the vHPC, but not in the dHPC (Alves *et al.*, 2004), reinforcing the idea that within the hippocampus the vHPC plays a primary role in regulation of anxious states. Further studies are required to fully explore the anxiolytic and anxiogenic effects of serotonergic compounds in the ventral hippocampus, and the receptor systems involved.

### *Effects of serotonin in panic circuitry*

Evidence suggests that there is an anatomical and functional topography of serotonergic neurons within the dorsal raphe nucleus (for review, see Lowry *et al.*, 2008a) (Figure 1). One of the most distinct anatomical and functional subsets of serotonergic neurons is that subset located within the 'lateral wings' of the dorsal raphe nucleus. These are large multipolar neurons that are scattered throughout the DRVL part of the dorsal raphe nucleus and the adjacent VLPAG. These cells are part of a sympathomotor command center, with multisynaptic connections to both hindlimb muscles and the adrenal medulla, and therefore are positioned to regulate multiple components of the 'fight-or-flight' or panic-like responses (Kerman *et al.*, 2006).

One site that may be involved in DRVL/VLPAG regulation of panic-like responses is the RVLM. DRVL/VLPAG serotonergic neurons project to the RVLM (Underwood *et al.*, 1999; Bago *et al.*, 2002), and chemical stimulation of the VLPAG region results in sympathoinhibition and hypotension. VLPAG stimulation-induced sympathoinhibition and hypotension can be blocked by microinjection of the 5-HT<sub>1A</sub> receptor antagonist WAY-100635 into the RVLM (Bago and Dean, 2001). In approximately half of the animals, microinjection of WAY-100635 into the RVLM not only prevented the VLPAG-induced sympathoinhibition and hypotension, but also evoked sympathoexcitation and hypertension (Bago and Dean, 2001). DRVL/VLPAG neurons also project to the DPAG (Stezhka and Lovick, 1997). Activation of 5-HT<sub>1A</sub> or 5-HT<sub>2</sub> receptors in the DPAG reduces the excitability of the DPAG and reduces panic-like behavioral responses (for review, see Graeff *et al.*, 1996). Thus, serotonergic projections arising from the DRVL/VLPAG region innervate a sympathomotor command center and appear to inhibit both autonomic and behavioral components of panic-like responses.

Functional anatomical studies support a role for the DRVL/VLPAG region in inhibition of panic-like responses.

We have shown that a number of panicogenic stimuli, including sodium lactate infusion (Johnson *et al.*, 2008) and exposure to hypercapnia (elevated concentrations of carbon dioxide in inhaled air; Johnson *et al.*, 2005), selectively increase c-Fos expression in the DRVL/VLPAG region (for review, see Johnson *et al.*, 2004). Importantly, we have found that infusion of sodium lactate, while it increases c-Fos expression in serotonergic neurons within the DRVL/VLPAG region in normal rats that do not respond to sodium lactate, has no effect on c-Fos expression in serotonergic neurons in panic-prone rats that respond to sodium lactate infusion with tachycardia and hypertension (Johnson *et al.*, 2008). These data are consistent with the hypothesis that serotonergic neurons in the DRVL/VLPAG region normally play a role in suppression of autonomic responses to panicogenic stimuli, but that failure to activate this serotonergic system disinhibits panic responses.

Adverse early life experience may result in vulnerability to stress-induced effects on the DRVL/VLPAG group of serotonergic neurons. We have shown that exposure of rats to a social defeat paradigm increased the expression of TPH2 and SERT mRNA expression, but that this effect was only apparent in rats that had been exposed to adverse early life experience (maternal separation) (Gardner *et al.*, 2006; Lowry *et al.*, 2008b). In contrast, stress had no effect on TPH2 or SERT mRNA expression in other regions of the dorsal raphe nucleus, even in rats exposed to maternal separation. These site-specific effects may be due to activation of specific afferent inputs to this region (Peyron *et al.*, 1998). Interestingly, when rats were pretreated with a 5-HT<sub>1A</sub> receptor antagonist, to prevent autoreceptor-mediated negative feedback to serotonergic neurons, exposure of rats to the forced swim test selectively increased c-Fos expression in serotonergic neurons in the DRVL/VLPAG region (Commons, 2008), consistent with the hypothesis that stimuli that evoke a passive emotional coping strategy (Keay and Bandler, 2001) activate DRVL/VLPAG serotonergic neurons.

### **Summary and future directions**

Anxious states can be induced by a number of pharmacological approaches or by adverse experience, during either development or adult life. Genetic influences and adverse early life experiences can result in stable individual differences in anxiety traits. These anxious states and anxiety traits appear to be controlled by a distributed network of interconnected brain regions, including the brainstem noradrenergic and serotonergic systems. We argue that in order to understand the role of serotonergic systems in the modulation of anxious states, it is important to identify

key nodes of anxiety circuitry, and to understand the properties of the subpopulation(s) of serotonergic neurons that projects to anxiety circuits. Using this approach, it is clear that a subset of serotonergic neurons, predominantly located in the mid-rostrocaudal and caudal parts of the dorsal raphe nucleus, projecting to the basolateral amygdala and ventral hippocampus, modulates anxiety states, while a different subset of serotonergic neurons in the lateral wings of the dorsal raphe nucleus, projecting to the DPAG and RVLM, is part of a sympathomotor command system regulating the fight-or-flight or panic response.

Future studies should clarify the role of different serotonin receptor subtypes within these different anxiety circuits in the regulation of anxious states and panic-like responses, and under what conditions these serotonergic systems are activated. Selective lesion of different subsets of serotonergic neurons should play an important role in clarifying some of these issues. If different subsets of serotonergic neurons have different molecular phenotypes, as might be suspected based on their different afferent input, molecular profiling of subsets of serotonergic neurons should provide opportunities for selective pharmacological manipulation of subsets of serotonergic neurons involved in modulation of anxious states, a strategy that could limit side effects. Future studies should investigate the interactions among genetic vulnerability, adverse early life experience and adverse experience during adulthood on serotonergic systems, anxious states and the development of anxiety traits. Finally, strategies should be explored for reversal of these anxiety states and anxiety traits.

# Role of Serotonin in Brain Reward and Regulation of Alcohol Drinking Behavior

W.J. McBride\*

*Institute of Psychiatric Research, Department of Psychiatry, Indiana University School of Medicine, Indianapolis, Indiana*

**Abstract:** This chapter will review the involvement of serotonin (5-HT) in mediating brain reward processes, and extend the review to the regulation of alcohol drinking by 5-HT. The first three sections of the chapter will focus on studies using intracranial self-stimulation, place conditioning, and conditioned reward and delay of reward procedures to examine the involvement of 5-HT in the regulation of brain reward systems. The fourth section will focus on studies of the involvement of 5-HT in regulating the rewarding properties of alcohol, as measured by alcohol drinking behavior of rodent models. Overall, the data suggest that 5-HT systems negatively modulate brain reward processes and alcohol drinking. However, some findings suggest that the effects of 5-HT on brain reward and alcohol drinking is dependent upon the subtype of 5-HT receptor.

**Keywords:** brain reward system; intracranial self-stimulation; place conditioning; conditioned reward; delay of reward; alcohol drinking behavior.

**Abbreviations:** AA, Alko-Alcohol; ACB, nucleus accumbens; CNS, central nervous system; CPA, conditioned place aversion; CPP, conditioned place preference; CR, conditioned reward; CS, conditioned stimulus; CTA, conditioned taste aversion; DA, dopamine; 5,7-DHT, 5,7-dihydroxytryptamine; DLR, delay of reward; DRN, dorsal raphe nucleus; EtOH, ethanol; FH, Fawn-Hooded; ICSA, intracranial self-administration; ICSS, intracranial self-stimulation; HAD, high-alcohol-drinking; 5-HT, serotonin; LAD, low-alcohol-drinking; LH, lateral hypothalamus; MFB, medial forebrain bundle; MPF, medial prefrontal cortex; MRN, median raphe nucleus; NP, alcohol non-preferring; 8-OH-DPAT, 8-hydroxy-2-(di-*n*-propylamino)-tetralin; P, alcohol preferring; PCPA, para-chlorophenylalanine; VP, ventral pallidum; VMT, ventral tegmentum; VTA, ventral tegmental area.

## Introduction

Serotonin (5-HT) has been implicated in modulating many behaviors and in regulating the reinforcing effects of certain drugs of abuse, such as cocaine and alcohol. The main sources of 5-HT are the dorsal and median raphe nuclei (DRN and MRN, respectively) located in the brainstem. Fibers from these nuclei project to almost all parts of the brain, suggesting the involvement of the 5-HT system in modulating many different functions. The widespread innervations from the DRN and MRN suggest that 5-HT is involved in many behaviors. Moreover, there are a high number of 5-HT receptor subtypes, suggesting that 5-HT involvement in modulating behaviors is likely to be highly complex and difficult to define clearly.

Brain reward systems incorporate multiple limbic pathways, most notably the medial forebrain bundle (MFB) and the lateral hypothalamus (LH). Within these pathways, the ventral tegmental area (VTA) dopamine (DA) projections to several regions, for example, the nucleus accumbens (ACB), ventral pallidum (VP) and medial prefrontal cortex (MPF), play important roles in mediating the rewarding actions of drugs of abuse, including alcohol, and are considered central structures in brain reward systems.

Several experimental approaches were used to examine the involvement of 5-HT in brain reward. The intracranial self-stimulation (ICSS) technique defines discrete brain sites that support electrical self-stimulation. With this technique, stimulating electrodes are stereotactically implanted into discrete brain sites; if the animal responds to receiving an electrical stimulation, then the site is supporting self-stimulation and the effects are considered reinforcing. This site may, therefore, be part of the brain

\*E-mail: wmcbride@iupui.edu

reward system. Using the ICSS technique in combination with pharmacological treatments can provide insights into the involvement of 5-HT in brain reward mechanisms.

Another approach is the intracranial self-administration (ICSA) procedure. The ICSA technique is a cross between the ICSS and operant drug self-administration. The ICSA procedure has been used to identify neuroanatomical substrates mediating the reinforcing effects of various drugs of abuse (McBride *et al.*, 1999). With this procedure, the animal responds to receiving the site-specific microinjection of a given pharmacological agent (e.g., cocaine, morphine, ethanol, etc.). The ICSS and ICSA procedures have been used to map CNS sites, neuronal pathways and neurotransmitter receptors involved in brain reward.

The place conditioning technique can be used to examine the positive or negative conditioning effects of a given treatment on the subsequent preference or aversion of a compartment previously associated with the treatment, but tested in the absence of the treatment. This technique has been used extensively to test whether pharmacological agents are reinforcing or aversive. With this technique, the animal is administered the test compound and is then placed in one compartment of a two- or three-compartment chamber. After three or four conditioning/treatment trials, the animal is placed in the two- or three-compartment apparatus without any treatment and allowed access to all compartments. If the animal prefers the compartment associated with the treatments, then the agent is producing a positive or rewarding effect (conditioned place preference, CPP). In contrast, if the animal avoids the compartment associated with the treatments, then the agent is considered to be producing negative or aversive effects (conditioned place aversion, CPA).

In the conditioned reward (CR) procedure, the animal responds to cues associated with a reward in the absence of the reward. Usually, with this procedure the animal is conditioned to a cue (conditioned stimulus, CS+), such as a tone or light, prior to receiving a reward (e.g., food, water, drug, etc.). With this procedure, the CS+ takes on rewarding characteristics of its own, as exemplified by the animal responding for the CS+ in the absence of the reward.

The above behavioral techniques, in combination with site-specific microinjections, have the potential of delineating the involvement of certain 5-HT pathways and receptors in modulating brain reward processes. This chapter will review the results of several experimental approaches that examined the involvement of 5-HT in regulating brain reward function.

The involvement of 5-HT systems in regulating alcohol drinking behavior has been studied in a number of animal models (see reviews by LeMarquand *et al.*, 1994; Li and McBride, 1995; McBride and Li, 1998; Murphy *et al.*, 2002). The final section of this chapter will review key

experiments on the involvement of 5-HT in regulating the reinforcing effects of alcohol and alcohol-drinking behavior.

## ICSS and ICSA studies and the effects of 5-HT

### *Effects of 5-HT on electrical self-stimulation of the LH and MFB*

Most ICSS studies use electrodes implanted in the LH or MFB, which activate DA pathways originating in the VTA (Rolls *et al.*, 1974; Gallistel *et al.*, 1982). Thus, studies designed to test 5-HT effects on ICSS with electrodes implanted in the LH or MFB are presumed to be testing effects on the activity of VTA DA pathways.

Studies on the effects of 5-HT on ICSS of the LH and MFB involved increasing or decreasing 5-HT synthesis, increasing extracellular 5-HT levels by increasing release or inhibiting reuptake, and administration of selective 5-HT receptor agonists or antagonists (Table 1). Increasing 5-HT synthesis with systemic administration of tryptophan or 5-hydroxytryptophan (5-HTP) reduced self-stimulation of the LH (Patkina and Lapin, 1976), whereas inhibiting 5-HT synthesis with para-chlorophenylalanine (PCPA) had no effect on ventral tegmentum (VMT) self-stimulation (Miliaressis, 1977) or self-stimulation of the LH (Van der Kooy *et al.*, 1977). These results suggest that 5-HT systems may have a role in modulating brain reward stimulation, although it is difficult to interpret the effects on 5-HT synthesis, because it is not known if these treatments significantly altered extracellular levels of 5-HT.

Several studies used pharmacological treatments with agents known to increase the extracellular levels of 5-HT, and tested the effects of these agents on brain electrical self-stimulation (Table 1). Dexfenfluramine and fenfluramine, which are known to increase the release of 5-HT, suppressed self-stimulation of the LH (Hoebel *et al.*, 1988) and MFB (Olds, 1995). In agreement with the results of the 5-HT releasing agents, the 5-HT reuptake inhibitor fluoxetine increased the threshold for electrical self-stimulation of the VTA or MFB (Lee and Kornetsky, 1998) and reduced the rates of self-stimulation of the MFB (Katz and Carroll, 1977). The combined results suggest that general activation of 5-HT pathways may have an inhibitory role on brain reward stimulation, involving the VTA DA system.

Several studies used 5-HT receptor agonists and antagonists to better understand the role of 5-HT in brain electrical self-stimulation (Table 1). Two of these studies examined the effects of systemic administration of 5-HT<sub>1A</sub> receptor agonists on ICSS of the LH (Montgomery *et al.*,

**Table 1** Involvement of 5-HT in brain reward as measured with intra-cranial self-stimulation and intra-cranial self-administration techniques

Treatment	CNS region	Results/conclusions	Reference
A. ICSS studies			
Tryptophan and 5-HTP; systemic; cats	LH	Increasing 5-HT synthesis reduced ICSS, suggesting that 5-HT exerts inhibitory effects on the brain reward system	Patkina and Lapin, 1976
PCPA; systemic	VMT or MRN	Inhibiting 5-HT synthesis reduced ICSS in MRN, but not in VMT; these results suggest that 5-HT neurons in the MRN may be involved in brain reward stimulation	Miliaressis, 1977
PCPA; systemic	HIP or LH	Inhibiting 5-HT synthesis reduced ICSS in HIP but not in LH; reward stimulation in the HIP mediated by 5-HT	Van der Kooy <i>et al.</i> , 1977
Dexfenfluramine; systemic	LH	Increasing 5-HT release inhibited ICSS; these results indicate that 5-HT exerts a negative effect on LH brain reward stimulation	Hoebel <i>et al.</i> , 1988
Fenfluramine, i.p., Sprague-Dawley rats	MFB	Fenfluramine suppressed ICSS, supporting the idea that 5-HT exerts an inhibitory effect on the brain reward system	Olds, 1995
Fluoxetine, i.p.	Caudal MFB	Inhibiting 5-HT reuptake reduced rates of ICSS; these results suggest that increasing extracellular levels of 5-HT will attenuate brain reward stimulation	Katz and Carroll, 1977
Fluoxetine, i.p.; Wistar rats	VTA or MFB	Inhibiting 5-HT reuptake increased the threshold for ICSS; these results indicate that increased extracellular levels of 5-HT can result in reduced sensitivity to brain reward stimulation	Lee and Kornetsky, 1998
8-OH-DPAT, buspirone; i.p.; Lister hooded rats	LH	Low-dose 8-OH-DPAT increased and high doses reduced ICSS; buspirone produced depression of ICSS; these results suggest that low 8-OH-DPAT doses reduce 5-HT activity via activation of 5-HT <sub>1A</sub> autoreceptors, resulting in increased ICSS; activation of postsynaptic 5-HT <sub>1A</sub> receptors suppresses ICSS	Montgomery <i>et al.</i> , 1991
8-OH-DPAT and p-MPPI; systemic	LH	The 5-HT <sub>1A</sub> agonist reduced ICSS threshold at low doses, but increased the threshold at higher doses; the 5-HT <sub>1A</sub> antagonist had no effect; these results suggest that LH stimulation does not involve activation of postsynaptic 5-HT <sub>1A</sub> receptors, but activation of these 5-HT <sub>1A</sub> receptors reduces brain reward stimulation	Harrison and Markou, 2001
RU24969 and GR127935; s.c.; Wistar rats	LH	The 5-HT <sub>1A/1B</sub> receptor agonist increased ICSS threshold, but the 5-HT <sub>1B/1D</sub> antagonist had no effect on ICSS; these results support the idea that LH stimulation does not involve activation of 5-HT <sub>1B</sub> receptors, but activation of 5-HT <sub>1B</sub> receptors can reduce brain reward stimulation	Harrison <i>et al.</i> , 1999
8-OH-DPAT, microinjection, MRN	LH	Microinjection of the 5-HT <sub>1A</sub> agonist into MRN reduced ICSS threshold; these results indicate that activating 5-HT <sub>1A</sub> receptors in MRN increases brain reward stimulation, suggesting that 5-HT projections from the MRN exert inhibitory influence on brain reward	Fletcher <i>et al.</i> , 1995
8-OH-DPAT; microinject, MRN, DRN	LH	The 5-HT <sub>1A</sub> agonist injected into the MRN reduced the ICSS threshold, but had no effect when injected into the DRN; these results indicate that activating 5-HT <sub>1A</sub> receptors in the MRN may be reducing 5-HT neuronal activity, suggesting 5-HT projections from MRN, but not DRN, are exerting inhibitory influence on brain reward stimulation	Harrison and Markou, 2001
M100907; systemic; Sprague-Dawley rats	LH	The 5-HT <sub>2A</sub> antagonist did not alter ICSS, indicating that activation of 5-HT <sub>2A</sub> receptors may not be involved in brain reward stimulation	Benaliouad <i>et al.</i> , 2007
Ondansetron, s.c.; rats	LH	The 5-HT <sub>3</sub> antagonist did not alter ICSS, indicating that activation of 5-HT <sub>3</sub> receptors may not be involved in brain reward stimulation	Herberg <i>et al.</i> , 1992
Ondansetron, s.c.	LH	The 5-HT <sub>3</sub> antagonist did not alter ICSS, supporting the idea that activation of 5-HT <sub>3</sub> receptors may not be involved in brain reward stimulation	Montgomery <i>et al.</i> , 1993

(Continued)

**Table 1** *Continued*

Treatment	CNS region	Results/conclusions	Reference
SB-204070-A; systemic; rats	LH	The 5-HT <sub>4</sub> antagonist did not alter ICSS; indicating that activation of 5-HT <sub>4</sub> receptors may not be involved in brain reward stimulation	Reavill <i>et al.</i> , 1998
PCPA, i.g., rats	DRN or MRN	Administration of the 5-HT synthesis inhibitor reduced ICSS in the DRN and MRN, suggesting that activation of 5-HT neurons are involved in self-stimulation of the DRN and MRN	Van der Kooy <i>et al.</i> , 1978
Metergoline, cypheptadine, PCA, 5,7-DHT	MRN	Non-selective 5-HT antagonists, depletion of 5-HT or destruction of 5-HT neurons had no effect on ICSS of MRN, suggesting that the rewarding effects of electrical stimulation in MRN do not appear to involve 5-HT neurons	Deakin, 1980
<b>B. ICSA studies</b>			
Muscimol, microinjection; rats	DRN, MRN	Muscimol was self-infused into the MRN and DRN, suggesting that activating GABA <sub>A</sub> receptors in the MRN and DRN is producing reinforcing effects, presumably thru inhibition of 5-HT neuronal activity	Liu and Ikemoto, 2007
1-(m-chloro-phenyl)-biguanide; microinjection; rats	VTA	The 5-HT <sub>3</sub> agonist is self-infused into the posterior VTA, suggesting that activation of 5-HT <sub>3</sub> receptors produces reinforcing effects	Rodd <i>et al.</i> , 2007

*Abbreviations:* ICSA, intracranial self-administration; ICSS, intracranial self-stimulation; LH, lateral hypothalamus; DRN, dorsal raphe nucleus; MRN, median raphe nucleus; PCA, para-chloro-amphetamine; PCPA, para-chlorophenylalanine; 5,7-DHT, 5,7-dihydroxytryptamine; 5-HTP, 5-hydroxytryptophan; 8-OH-DPAT, 8-hydroxy-2-(di-*n*-propylamino)-tetralin; HIP, hippocampus; VMT, ventral tegmentum; MFB, medial forebrain bundle; VTA, ventral tegmental area; s.c., subcutaneous; i.g., intragastric; i.p., intraperitoneal.

1991; Harrison and Markou, 2001). These studies reported that the 5-HT<sub>1A</sub> agonist 8-hydroxy-2-(di-*n*-propylamino)-tetralin (8-OH-DPAT) produced a biphasic effect on ICSS of the LH, with low doses increasing responding and lowering the threshold for ICSS, and higher doses reducing responding and increasing the threshold for ICSS. Low doses of 8-OH-DPAT are thought to act at 5-HT<sub>1A</sub> autoreceptors (Dourish *et al.*, 1988), whereas higher doses act at both presynaptic 5-HT<sub>1A</sub> autoreceptors and postsynaptic 5-HT<sub>1A</sub> receptors. Therefore, the results of the 5-HT<sub>1A</sub> receptor agonist studies suggest that activating postsynaptic 5-HT<sub>1A</sub> receptors reduces brain reward stimulation, whereas inhibiting 5-HT neuronal activity, via activation of cell body 5-HT<sub>1A</sub> autoreceptors, enhances brain reward stimulation. Consistent with the postsynaptic effects of 8-OH-DPAT on 5-HT<sub>1A</sub> receptors, activation of 5-HT<sub>1B</sub> receptors, with systemic administration of a 5-HT<sub>1B</sub> receptor agonist, increased the threshold for self-stimulation of the LH (Harrison *et al.*, 1999), suggesting that activation of 5-HT projections to postsynaptic 5-HT<sub>1B</sub> receptors can also inhibit LH self-stimulation (Table 1).

To test the hypothesis that activating 5-HT<sub>1A</sub> autoreceptors will enhance self-stimulation of the LH, Fletcher *et al.* (1995) and Harrison and Markou (2001) examined the direct effect of microinjecting 8-OH-DPAT into the MRN on ICSS of the LH (Table 1). Both studies reported that microinjecting 8-OH-DPAT into the MRN reduced the threshold for self-stimulation of the LH, suggesting that inhibiting 5-HT neuronal activity in the MRN, by activating 5-HT<sub>1A</sub> autoreceptors with 8-OH-DPAT, enhances

brain reward stimulation. On the other hand, microinjecting 8-OH-DPAT into the DRN had no significant effect on the ICSS of the LH (Harrison and Markou, 2001). The results observed with microinjecting 8-OH-DPAT into the MRN are compatible with the results reported above for 5-HT releasers and reuptake inhibitors, and support an interpretation that the 5-HT system from the MRN plays an inhibitory role in regulating the rewarding effects of stimulating the mesolimbic DA system.

Systemic administration of 5-HT<sub>1A</sub> (Harrison and Markou, 2001), 5-HT<sub>1B</sub> (Harrison *et al.*, 1999), 5-HT<sub>2A</sub> (Benaliouad *et al.*, 2007), 5-HT<sub>3</sub> (Herberg *et al.*, 1992; Montgomery *et al.*, 1993) or 5-HT<sub>4</sub> (Reavill *et al.*, 1998) receptor antagonists had little effect on MFB or LH self-stimulation (Table 1). These results suggest that any tonic activation of these receptors within this part of the brain reward system is not having a significant effect on modulating electrical self-stimulation of the MFB or LH. It is possible that other subtypes of 5-HT receptors may be involved, and/or the effects of 5-HT may be on accumulated actions at multiple receptors, such that inhibiting only one receptor at a time may not be sufficient to alter electrical self-stimulation of the LH or MFB.

### ***5-HT and electrical self-stimulation of the hippocampus, MRN and DRN***

Numerous studies indicate that multiple brain regions can support reinforcement processes (reviewed in McBride

*et al.*, 1999), including the hippocampus and MRN. Van der Kooy *et al.* (1977) reported that the hippocampus supported electrical self-stimulation, and that systemic administration of the 5-HT synthesis inhibitor PCPA reduced self-stimulation of this region (Table 1). Miliaressis (1977) reported that the MRN supported self-stimulation and that inhibition of 5-HT synthesis reduced self-stimulation of this region. In addition, Van der Kooy *et al.* (1978) reported that both the MRN and DRN supported electrical self-stimulation and that PCPA also reduced self-stimulation of these raphe nuclei (Table 1). The results of these studies suggest that activation of 5-HT systems promotes self-stimulation of the hippocampus and raphe nuclei. In contrast, another study (Deakin, 1980) reported that non-selective 5-HT receptor antagonists, depletion of 5-HT, or destruction of 5-HT neurons had little effect on electrical self-stimulation of the MRN (Table 1), suggesting that 5-HT neurons may not be involved. It is difficult to reconcile the differences between the studies; it is possible that differences in the placement of electrodes may account for the discrepancies between the studies. In the study of Deakin (1980), the electrodes may be stimulating fibers of passage, and therefore little effect was observed by destroying 5-HT neurons.

#### **ICSA studies: 5-HT involvement in brain reward**

Few studies have been carried out with the ICSA technique to study the involvement of 5-HT in brain reward mechanisms. Liu and Ikemoto (2007) reported that muscimol, a GABA<sub>A</sub> receptor agonist, was self-infused into the MRN and DRN of Wistar rats (Table 1). Activating GABA<sub>A</sub> receptors within the raphe nuclei will likely inhibit 5-HT neuronal activity. Therefore, if this is the case, then inhibiting 5-HT neuronal activity may remove tonic inhibition of the mesolimbic DA system; this disinhibition results in activation of brain reward processes. These results are compatible with the majority of studies cited above for an inhibitory effect of 5-HT on electrical self-stimulation of the LH and MFB. However, this ICSA study is at odds with the ICSS results indicating the MRN and DRN support electrical self-stimulation (Van der Kooy *et al.*, 1978; Miliaressis, 1977), unless electrical self-stimulation of the raphe nuclei is producing its effect via activation of GABA interneurons. However, electrical self-stimulation of raphe nuclei may also activate fibers of passage or adjacent structures, which could account of the results of electrical self-stimulation of the raphe nuclei (Miliaressis, 1977; Van der Kooy *et al.*, 1978).

Another ICSA study (Rodd *et al.*, 2007) indicated that a 5-HT<sub>3</sub> agonist was self-infused into the posterior VTA (Table 1), suggesting that activation of local 5-HT<sub>3</sub> recep-

tors is producing reinforcing effects. Moreover, the results of this study suggest that local activation of DA neurons is involved in mediating the reinforcing effects of the 5-HT<sub>3</sub> agonist. Although these results support an involvement of the 5-HT system in brain reward mechanisms, they are somewhat counter to the overall evidence that suggests activating the 5-HT system may inhibit brain reward stimulation. However, the influence of the 5-HT system on different processes is likely to be complex, and dependent in part on the subtype of 5-HT receptor and the CNS region.

In summary, the data support a mainly inhibitory role for 5-HT in brain reward stimulation. However, most studies supporting this view were conducted with local electrical self-stimulation of the mesolimbic DA system. On the other hand, the results of some studies suggest that the MRN and DRN can also support reinforcement processes and may be part of the brain reward system.

#### **Place conditioning and effects of 5-HT**

The rewarding and aversive effects of drugs of abuse and many other compounds have been studied using place conditioning. With the place conditioning paradigm, the intrinsic effects of the agent are paired with a previously neutral environment during the conditioning trials. If the effects of the compound are positive or rewarding, then the animal will spend more time in the environment previously associated with the drug effects, when tested in the absence of the drug. Conversely, if the agent produces a negative or aversive effect, then the animal will spend less time in the environment previously associated with drug administration, when tested in the absence of the drug. The place conditioning procedure has been used extensively to evaluate the positive and negative effects of a wide variety of compounds. Comprehensive reviews of the use of the place conditioning paradigm have been published (Tzschentke 1998, 2007).

Several studies were undertaken to assess the effects of increasing the extracellular levels of 5-HT on place conditioning (Table 2). In two studies (Davies and Parker, 1993; Rea *et al.*, 1998), the effects of the 5-HT releaser fenfluramine were tested in rats, and found to produce CPA, suggesting that 5-HT overflow is producing aversive effects. On the other hand, a third study (Meehan and Schechter, 1994) reported that fenfluramine failed to produce either CPP or CPA in Sprague-Dawley rats, although these investigators found that fenfluramine produced CPA in Fawn-Hooded (FH) rats. Differences in the experimental protocols may account in part for the disagreement between the studies with Sprague-Dawley rats.

Risinger (1997) tested the effects of the 5-HT reuptake inhibitor fluoxetine on place conditioning in mice, and

**Table 2** Involvement of 5-HT in brain reward as measured with place conditioning or conditioned taste aversion

Treatment	Measurement	Results/conclusions	Reference
Fenfluramine; i.p.; Sprague-Dawley rats	CPA	Administration of fenfluramine produced CPA, suggesting that increasing extracellular 5-HT levels produced aversive effects	Davies and Parker, 1993
Fenfluramine, systemic; Sprague-Dawley rats	CPP, CPA	Fenfluramine failed to produce CPP or CPA, suggesting that increasing extracellular levels of 5-HT had little effect on the brain reward or aversion systems	Meehan and Schechter, 1994
Fenfluramine; systemic; rats	CPP, CPA	Fenfluramine produced dose-related CPA, indicating that increasing extracellular levels of 5-HT produces aversive effects	Rea <i>et al.</i> , 1998
Fluoxetine, systemic; mice	CPP, CTA	Administration of the 5-HT reuptake inhibitor had no effect on either measure; these results indicate that increasing the extracellular 5-HT levels has little effect on brain reward or aversion systems in mice	Risinger, 1997
Paroxetine, fluoxetine, sertraline; systemic; Wistar rats	CPP	All three 5-HT reuptake inhibitors produced significant CPP; these results suggest that elevating extracellular 5-HT can produce rewarding effects	Subhan <i>et al.</i> , 2000
8-OH-DPAT; systemic	CPP, CPA	Low doses of 8-OH-DPAT produced CPP; high doses produced CPA; low dose but not high dose effects blocked by PCPA and DA antagonists; supporting the idea that low dose 8-OH-DPAT acting thru 5-HT <sub>1A</sub> autoreceptor inhibition of 5-HT activity, whereas high dose effects are at postsynaptic 5-HT <sub>1A</sub> receptors	Papp and Willner, 1991
CP 94,253, GR127935, systemic	CPP, CPA	Administration of a 5-HT <sub>1B</sub> agonist produced CPA, whereas a partial 5-HT <sub>1B</sub> agonist had no effect; these results suggest that activating 5-HT <sub>1B</sub> receptors produces aversive effects	Cervo <i>et al.</i> , 2002
TFMPP, WAY161503; s.c.; Sprague-Dawley rats	CPP	Neither the mixed 5-HT <sub>1A/1B/2C</sub> receptor agonist, TFMPP, nor the 5-HT <sub>2C</sub> agonist, WAY161503, induced place conditioning; these results suggest that activating 5-HT <sub>2C</sub> receptors is not producing rewarding effects	Mosher <i>et al.</i> , 2005
WAY161503, s.c.; Sprague-Dawley rats	CPA, CTA	Administration of the 5-HT <sub>2C</sub> agonist induced CPA and CTA, suggesting activation of 5-HT <sub>2C</sub> receptors produces aversion	Mosher <i>et al.</i> , 2006
Mianserine, eltoprazine, ketanserine, mCPP; i.p.; rats	CPP, CPA	The 5-HT <sub>1C</sub> agonist had little effect on CPP, CPA, whereas 5-HT <sub>1C</sub> antagonists produced CPA; the 5-HT <sub>2</sub> antagonist had little effect; these results indicate that inhibiting 5-HT <sub>1C</sub> receptors produces aversive effects, suggesting that 5-HT <sub>1C</sub> receptors may be having a positive tonic influence on brain reward processes	Rocha <i>et al.</i> , 1993a
Mianserine, i.p.; 5,7-DHT lesions; rats	CPA	Destruction of 5-HT neurons enhanced CPA produced by the 5-HT <sub>1C</sub> antagonist; reduced activation of 5-HT <sub>1C</sub> receptors enhances aversive effects	Rocha <i>et al.</i> , 1993b
8-OH-DPAT, microinjection; DRN, MRN	CPP	Microinjecting a 5-HT <sub>1A</sub> agonist into DRN or MRN produces CPP; indicating that inhibition of 5-HT neuronal activity produces reinforcing effects; these results suggest that both 5-HT systems exert tonic inhibitory effects on the brain reward system	Fletcher <i>et al.</i> , 1993
Muscimol, microinjection, MRN, DRN, rats	CPP	Administration of the GABA <sub>A</sub> agonist into the MRN produced CPP, whereas injection into the DRN did not, suggesting that inhibiting MRN 5-HT neurons produces rewarding effects	Liu and Ikemoto, 2007
Muscimol, microinjection, MRN	CPP	Activating GABA <sub>A</sub> receptors in the MRN did not produce CPP; these results suggest that inhibiting 5-HT neurons in the MRN does not activate brain reward processes	Le <i>et al.</i> , 2008

*Abbreviations:* DRN, dorsal raphe nucleus; MRN, median raphe nucleus; CPP, conditioned place preference; CTA, conditioned taste aversion; CPA, conditioned place aversion; mCPP, 5-HT<sub>1C</sub> agonist; PCPA, para-chlorophenylalanine; 8-OH-DPAT, 8-hydroxy-2-(di-*n*-propylamino)-tetralin; TFMPP, mixed 5-HT<sub>1A/1B/2C</sub> receptor agonist; i.p., intraperitoneal; s.c., subcutaneous.

found no effect on either CPP or CPA (Table 2). In contrast, Subhan *et al.* (2000) tested three 5-HT reuptake inhibitors (paroxetine, fluoxetine and sertraline) on place conditioning in Wistar rats, and reported that all three reuptake inhibitors produced CPP. These results suggest that activating 5-HT systems in the rat produces rewarding effects, but this may not be the case for mice.

The results with the 5-HT releaser fenfluramine and 5-HT reuptake inhibitors are not in agreement. Administration of a 5-HT releaser produced CPA (Davies and Parker, 1993; Rea *et al.*, 1998), whereas the 5-HT reuptake inhibitors (Subhan *et al.*, 2000) produced CPP (Table 2). The differences between the two treatments may reflect their relative specificities and/or modes of action. Fenfluramine blocks uptake but it also accelerates release, causing higher extracellular levels of 5-HT at both 'active' and 'inactive' synapses. Reuptake inhibitors have their most significant effects on extracellular levels of 5-HT at 'active' synapses. Therefore, the 5-HT reuptake inhibitors may be enhancing 5-HT effects at selected synapses, whereas fenfluramine is increasing 5-HT at most 5-HT synapses, including those that are producing aversive effects, which may mask any positive actions. Furthermore, non-specific effects of these compounds on other monoamine systems may be having a significant role in their actions.

Systemic administration of agonists for 5-HT<sub>1A</sub>, 5-HT<sub>1B</sub> and 5-HT<sub>2C</sub> receptors was also tested in the place conditioning paradigm (Table 2). The 5-HT<sub>1A</sub> agonist 8-OH-DPAT, at low doses, produced CPP, but at high doses produced CPA (Papp and Willner, 1991). The low-dose effect is postulated to result from selective activation of cell body 5-HT<sub>1A</sub> autoreceptors, which reduces 5-HT neuronal activity. The high-dose effect is thought to result from the action of 8-OH-DPAT at postsynaptic 5-HT<sub>1A</sub> receptors. These results are similar to the effects of 8-OH-DPAT on ICSS of the LH (Montgomery *et al.*, 1991; Harrison and Markou, 2001). Administration of a 5-HT<sub>1B</sub> (Cervo *et al.*, 2002) or a 5-HT<sub>2C</sub> (Mosher *et al.*, 2006) receptor agonist produced CPA (Table 2). In addition, a mixed 5-HT<sub>1A,1B,2C</sub> agonist did not produce place conditioning (Mosher *et al.*, 2005). Administration of a 5-HT<sub>1C</sub> receptor agonist had little effect on CPP or CPA (Rocha *et al.*, 1993a), whereas inhibiting 5-HT<sub>1C</sub> receptors produced CPA (Rocha *et al.*, 1993a, 1993b). The inhibition of 5-HT<sub>2</sub> receptors with non-selective antagonists had little effect on CPP or CPA (Rocha *et al.*, 1993a). Overall, these results suggest that activating postsynaptic 5-HT<sub>1A</sub>, 5-HT<sub>1B</sub> or 5-HT<sub>2C</sub> receptors can produce aversive effects (Table 2). On the other hand, inhibiting 5-HT<sub>1C</sub> receptors produces aversive effects, suggesting that this subtype of receptor may be actively involved in positive modulation of brain reward processes.

The results with the 5-HT agonists producing CPA (Cervo *et al.*, 2002; Mosher *et al.*, 2005, 2006), or with the low-dose effects of 8-OH-DPAT producing CPP (Papp and Willner, 1991), are not compatible with the actions of 5-HT reuptake inhibitors (Subhan *et al.*, 2000) producing CPP (Table 2). It is difficult to reconcile these differences, since the increased extracellular 5-HT produced by the reuptake inhibitors would be expected to occur at 5-HT<sub>1A</sub>, 5-HT<sub>1B</sub> and 5-HT<sub>2C</sub> receptors. It is possible that the reuptake inhibitors may be having their main effects at certain active 5-HT synapses involving 5-HT<sub>1C</sub> or other 5-HT receptor subtypes. Alternatively, the 5-HT reuptake inhibitors may be having their initial effects at cell body 5-HT<sub>1A</sub> autoreceptors, thereby reducing 5-HT neuronal activity.

Several microinjection studies were undertaken to examine the effects of inhibiting 5-HT neuronal activity in the raphe nuclei on place conditioning (Table 2). Fletcher *et al.* (1993) reported that microinjection of the 5-HT<sub>1A</sub> receptor agonist 8-OH-DPAT, into either the MRN or the DRN, produced CPP. Liu and Ikemoto (2007) reported that microinjection of the GABA<sub>A</sub> receptor agonist muscimol into the MRN produced CPP, whereas injection into the DRN did not. In contrast, Le *et al.* (2008) reported that microinjection of muscimol into the MRN did not produce CPP. The apparent discrepancy between the latter two studies may be due to differences in the placement of the injection cannula and the experimental paradigm. Microinjection of 8-OH-DPAT and muscimol into the raphe nuclei would be expected to reduce 5-HT neuronal activity. The results of the microinjection studies suggest that reducing 5-HT neuronal activity enhances rewarding effects. These findings are compatible with most of the ICSS studies and with the place conditioning studies, using systemic injections, and support a mainly inhibitory role for 5-HT regulation of brain reward.

## **Involvement of 5-HT in conditioned reward and delay of reward**

### ***Conditioned reward and 5-HT***

Increased incentive motivation refers to the process by which appetitive behaviors are produced by rewarding stimuli (Beninger, 1983; Fibiger and Phillips, 1986). The conditioned reward (CR) paradigm has been used to study incentive motivation. In this paradigm, an initial neutral stimulus is paired with a primary reinforcer; after several pairings, the animals are given access to two levers, an inactive lever and a lever that delivers the CR. Incentive motivation is demonstrated when the responses on the CR lever are significantly higher than responses

on the inactive lever. Several studies indicate a role for dopaminergic systems in mediating CR (see, for example, Robbins, 1978; Beninger, 1983; Robbins *et al.*, 1983; Fibiger and Phillips, 1986; Beninger and Rinaldi, 1992). Since changes in the 5-HT system modify reward-related behavioral responses to drugs acting on the DA system (e.g., Smith *et al.*, 1986, 1987; Carroll *et al.*, 1990), a logical next step would be to conduct studies examining the involvement of 5-HT in CR (Table 3).

Fletcher (1995) examined the effects of d-fenfluramine, a 5-HT releaser, on water-deprived Sprague-Dawley rats (Table 3). In this study, water-deprived rats were trained to associate a compound stimulus (light and tone) with water during the conditioning phase. During the test phase, water was not delivered, but the compound stimulus was delivered when the correct lever was pressed. Systemic administration of d-fenfluramine reduced responding for the CR (Fletcher, 1995), suggesting that increasing 5-HT release was attenuating the conditioned reinforcing effects of the compound stimulus.

Sasaki-Adams and Kelley (2001) examined the effects of chronic fluoxetine, a 5-HT reuptake inhibitor, in a CR paradigm, in which Sprague-Dawley rats were trained to associate a compound stimulus (light and click of food dispenser) with the delivery of a sugar pellet. During CR testing, the compound stimulus, but not the sugar pellet, was delivered when the correct lever was pressed. Administration of fluoxetine increased responding on the active lever for the conditioned stimulus (Table 3), which is not in agreement with the results with d-fenfluramine (Fletcher, 1995). Since both d-fenfluramine and fluoxetine increase the extracellular levels of 5-HT, their differential effects on CR may be due to a combination of factors – e.g., acute versus chronic drug administration, and/or 5-HT being released by fenfluramine at essentially all 5-HT synapses, whereas the greater effects of the 5-HT reuptake inhibitor are at ‘active’ 5-HT synapses.

In a follow-up study, Fletcher *et al.* (1999) examined the effects of selective 5,7-DHT lesions of both the MRN and DRN on responding in a CR paradigm (compound stimulus of light and tone associated with delivery of water in water-deprived Sprague-Dawley rats). In support of the findings of the d-fenfluramine study (Fletcher, 1995), the combined 5-HT lesions of the MRN and DRN significantly enhanced responding on the active lever in the CR test (Table 3). Overall, these results support the idea that general activation of 5-HT systems may decrease incentive motivation. Although some parts of the 5-HT system may be actively involved in a positive manner on CR, activation of the majority of 5-HT synapses may produce negative effects and counter any positive actions of 5-HT.

Fletcher and Higgins (1997) reported that administration of ondansetron, a 5-HT<sub>3</sub> receptor antagonist, did not

alter learning a CR (Table 3), suggesting that activation of 5-HT<sub>3</sub> receptors is not involved in this process.

### *Delay of reward and 5-HT*

When choosing between a larger but delayed reward and a smaller but more immediate reward, a comparison is made between the ‘values’ associated with each reward, and the reward associated with the larger value is often chosen (Platt, 2002). The possible involvement of 5-HT in the timescale of reward prediction has been briefly reviewed (Schweighofer *et al.*, 2007).

Fletcher (1993) determined the effects of microinjecting 8-OH-DPAT (to activate local cell body 5-HT<sub>1A</sub> autoreceptors and reduce 5-HT neuronal activity) into the MRN and DRN of Sprague-Dawley rats on responding in two different operant paradigms – i.e., extinction responding and during omission training (delay of reward paradigm). Microinjection of 8-OH-DPAT into the DRN did not significantly alter responding in either behavioral paradigm, whereas microinjection of 8-OH-DPAT into the MRN increased extinction responding, enhanced operant performance during omission training, and slightly increased responding during periods of non-reward (Table 3). To provide additional data that the effects of 8-OH-DPAT were a result of inhibition of 5-HT neuronal activity, Fletcher (1993) reported that microinjection of muscimol (a GABA<sub>A</sub> agonist) into the MRN also increased extinction responding. These results could be interpreted to indicate that MRN 5-HT neurons, but not DRN 5-HT neurons, may be involved in controlling behavioral inhibition under conditions of non-reward.

In agreement with the above study, Wogar *et al.* (1993) reported that the combined 5,7-DHT lesions of the MRN and DRN shortened the delay to the larger reinforcer so that the short and delayed reinforcer were equally effective (Table 3). Similar findings were reported by Al-Ruwaitea *et al.* (1999) and Bizot *et al.* (1999), in which 5,7-DHT lesions of the raphe nuclei reduced the number of choices for the larger but delayed reward over the smaller but more immediate reward (Table 3). Taking the opposite approach, Bizot *et al.* (1999) found that increasing the extracellular levels of 5-HT by administration of fluoxetine increased preference for the larger but delayed reward (Table 3). These results suggest that increased activity of the 5-HT system may improve the effectiveness of a larger but delayed reward, possibly indicating more controlled and less impulsive behavior.

Inhibition of 5-HT neuronal activity and activation of postsynaptic 5-HT<sub>1A</sub> receptors following systemic administration of 8-OH-DPAT decreased performance for long delays (6 and 12 s) and increased performance for a

**Table 3** Modulation of conditioned reward and delay of reward by 5-HT

Treatment	Procedure	Results/conclusions	Reference
d-fenfluramine; i.p.; Sprague-Dawley rats	CR	Increased extracellular levels of 5-HT reduced responding for the CR, suggesting that 5-HT has an inhibitory action on brain reward circuitry	Fletcher, 1995
Fluoxetine, systemic, rats	CR	Increased extracellular levels of 5-HT enhanced CR responding; these results suggest that 5-HT facilitated reward-related behavior	Sasaki-Adams and Kelley, 2001
5,7-DHT lesions of both DRN, MRN; Sprague-Dawley rats	CR	Depletion of 5-HT innervation increased responding for CR, supporting the idea that 5-HT exerts an inhibitory influence on reward processes	Fletcher <i>et al.</i> , 1999
Ondansetron, systemic, rats	CR	Inhibiting 5-HT <sub>3</sub> receptors does not alter learning CR; these results suggest that 5-HT <sub>3</sub> receptors are not involved with learning a CR	Fletcher and Higgins, 1997
8-OH-DPAT, microinjection MRN, DRN; Sprague-Dawley rats	DLR	Inhibiting 5-HT activity in the MRN increased responding during extinction, during delay of reward, and for non-reward; these results indicate that the MRN 5-HT system may be involved in controlling behavioral inhibition by detecting signals of non-reward	Fletcher, 1993
5,7-DHT lesions, both MRN and DRN	DLR	Lesions shortened the delay to the larger reward that rendered the short and delayed reward equally effective; these results suggest that the 5-HT systems are involved in maintaining the effectiveness of delayed reinforcers	Wogar <i>et al.</i> , 1993
5,7-DHT, microinjection, both DRN, MRN	DLR	Reduction of 5-HT innervation increased the time within a trial at which proportional choice of the delayed reward attained a value of 50% of the shorter reward; these results indicate that 5-HT system exerts control (inhibition) of behavior of delayed reward	Al-Ruwaitea <i>et al.</i> , 1999
5,7-DHT in DRN; PCPA treatment; 8-OH-DPAT, buspirone, ipsapirone, MDL73005EF, fluoxetine; i.p.	DLR	Reduced 5-HT innervation from the DRN and reduced 5-HT synthesis caused a shift toward immediate reward; activating 5-HT <sub>1A</sub> receptors and increasing extracellular 5-HT increased preference for the larger but delayed reward; blocking 5-HT <sub>1A</sub> receptors had no effect on preference; these results suggest that the 5-HT system may be involved in modulating pathways that evaluate reward value	Bizot <i>et al.</i> , 1999
8-OH-DPAT, systemic, rats	DLR	Activating 5-HT <sub>1A</sub> receptors increased lever press performance for a short delay; these results suggest that activating postsynaptic 5-HT <sub>1A</sub> receptors and/or reducing 5-HT neuronal activity improves performance during a short delay for reward	Balleine <i>et al.</i> , 1996

*Abbreviations:* CR, conditioned reward; DLR, delay of reward; MRN, median raphe nucleus; DRN, dorsal raphe nucleus; 5,7-DHT, 5, 7-dihydroxytryptamine; PCPA, para-chlorophenylalanine; 8-OH-DPAT, 8-hydroxy-2-(di-*n*-propylamino)-tetralin; i.p., intraperitoneal.

short (3-s) delay (Balleine *et al.*, 1996). In contrast to the results of this latter study, Bizot *et al.* (1999) reported that systemic administration of 8-OH-DPAT increased preference for the larger but delayed (25 s) reward. The length of the delay may be the main factor that contributes to the apparent disagreement between the two studies. Bizot *et al.* (1999) reported that, with a 15-s delay, 8-OH-DPAT had a small effect in reducing the number of choices for the larger reward, but with a 25-s delay, 8-OH-DPAT significantly increased preference for the larger reward. The effects of partial 5-HT<sub>1A</sub> receptor agonists were also

dependent on the length of the delay (Bizot *et al.*, 1999). The differences in the effects of 8-OH-DPAT between the studies of Balleine *et al.* (1996) and Bizot *et al.* (1999) appear to be due to the differences in delay to the larger reward, with the longer delay being more sensitive to the effects of 8-OH-DPAT. These results suggest that the 5-HT system may have a role in evaluating the incentive value of a reward, and modulating control of behavior of immediate gratification. It is difficult to interpret the effects of 8-OH-DPAT on delay of reward, since systemic injection of this agonist will likely act at both cell

body autoreceptors and postsynaptic 5-HT<sub>1A</sub> receptors. Therefore, the combination of reducing 5-HT neuronal activity and activating postsynaptic 5-HT<sub>1A</sub> receptors likely underlies the effects of 8-OH-DPAT on delay of reward.

### ***Summary/conclusions – involvement of 5-HT in brain reward***

Serotonin has a major role in modulating many different behaviors. It exerts significant modulation on the mesolimbic DA system, with evidence for both inhibitory and excitatory effects, depending upon the 5-HT receptor. The findings with electrical self-stimulation of the LH or MFB (which activates the mesolimbic DA system) indicate that reducing activity of MRN and DRN 5-HT neurons increases brain reward stimulation, suggesting that these 5-HT pathways exert a general inhibitory control on the mesolimbic reward system (Table 1). A similar conclusion of a general inhibitory effect of 5-HT on brain reward is supported by place conditioning studies. However, place conditioning studies have an advantage in that this procedure can measure both the rewarding and aversive effects of pharmacological agents. Reducing 5-HT neuronal activity (e.g., microinjecting 8-OH-DPAT into the raphe nuclei) promoted CPP, whereas some studies reported that increasing the extracellular levels of 5-HT (e.g., with fenfluramine) promoted CTA, although this was not observed in other cases (Table 2). In agreement with the findings reported for ICSS and place conditioning, studies with CR found that reduced 5-HT innervation increased responding for a CR (Fletcher *et al.*, 1999), whereas increased release of 5-HT (Fletcher, 1995) reduced responding for a CR (Table 3). The studies using DLR paradigms (Table 3) suggest that 5-HT systems are also involved in assessing the incentive value of a reward, with reduced 5-HT innervation decreasing the preference for longer delays with larger rewards, and increased extracellular levels of 5-HT increasing preference for the longer delays and larger rewards (Bizot *et al.*, 1999).

### **Involvement of 5-HT in regulation of alcohol drinking behavior in rodent models**

In some rat lines selectively bred for high or low alcohol consumption, there appear to be innate differences in 5-HT systems (Table 4). Initial findings in the selectively bred alcohol-preferring (P) and alcohol-non-preferring (NP) lines indicated that there were reduced tissue levels of 5-HT in CNS regions of the P compared to NP rats (Murphy *et al.*, 1982, 1987). Similar differences in CNS tissue

levels were also reported for high-alcohol-drinking (HAD) compared to low-alcohol-drinking (LAD) rats (Gongwer *et al.*, 1989), although in other selectively bred rat lines such widespread differences were not observed (reviewed in McBride and Li, 1998; Murphy *et al.*, 2002; see also Devoto *et al.*, 1998). The lower contents of 5-HT in the CNS of P compared to NP rats appear to be due to reduced 5-HT innervation to these regions, which was a result of fewer 5-HT raphe neurons in the P compared to NP rats (Zhou *et al.*, 1991a, 1991b, 1994), suggesting a general overall reduction in 5-HT modulation of CNS function in the P than NP rat. This reduced effect of 5-HT may promote higher ethanol (EtOH) intakes in the P and HAD lines of rats. In agreement with this interpretation, Yoshimoto and Komura (1987) reported a significant inverse correlation between whole brain levels of 5-HT and alcohol intake of inbred and congenic mouse strains (Table 4).

If there is an inverse relationship between CNS 5-HT function and alcohol intake, then increasing CNS 5-HT function should result in decreased EtOH intake. Several studies examined the effects of increasing extracellular levels of 5-HT or giving agonists selective for subtypes of 5-HT receptors on EtOH intake in different rodent alcohol-drinking models (Table 4). Administration of the 5-HT reuptake inhibitor fluoxetine reduced EtOH drinking of P and HAD rats (Murphy *et al.*, 1985, 1988; McBride *et al.*, 1990, 1992), suggesting that increasing 5-HT function in these 5-HT deficient rat lines reduces their high-alcohol-drinking characteristics. In agreement with the findings with the 5-HT reuptake inhibitor, several studies (Rowland and Morian, 1992; Rezvani and Grady, 1994; Yu *et al.*, 1997) reported that administration of the 5-HT releaser fenfluramine also reduced EtOH intake in P, Fawn-Hooded (FH) and alcohol-dependent rats (Table 4).

Conversely, if general CNS 5-HT function is reduced in a 'normal' population of rats, then the above hypothesis would predict an increase in EtOH intake. Two experimental approaches that would produce a general reduction in 5-HT function would be 5,7-DHT lesions of raphe nuclei, and inhibiting 5-HT neuronal activity within the raphe nuclei, using microinjections of 5-HT<sub>1A</sub> or GABA<sub>A</sub> receptor agonists. Lesions of the MRN and DRN, which reduced 5-HT levels more than 90 percent, did not alter EtOH intake of Sprague-Dawley rats (Adell and Myers, 1995). In contrast to these latter findings, reducing 5-HT neuronal activity, by microinjecting a 5-HT<sub>1A</sub> or GABA<sub>A</sub> receptor agonist into either the MRN or DRN, increased EtOH intake of Wistar rats during a 40-minute scheduled access period (Tomkins *et al.*, 1994a; Tomkins and Fletcher, 1996). The contradictory findings between the studies of Tomkins and co-workers and that of Adell and Myers (1995) may be a result of a combination of factors. For example, under 24-hour continuous access conditions,

Treatment	Measurement	Results/conclusions	Reference(s)
5-HT <sub>2C</sub> agents; agonist: RO 60-0175, s.c.; antagonist: SB242,084, i.p.; Wistar rats	Operant FR-4; 12% EtOH	Activating 5-HT <sub>2C</sub> receptors reduces EtOH responding, whereas inhibiting 5-HT <sub>2C</sub> receptors increases responding; these results suggest that 5-HT <sub>2C</sub> receptors may be involved in limiting EtOH drinking	Tomkins <i>et al.</i> , 2002
5-HT <sub>3</sub> antagonists: MDL72222; ICS 205-930; s.c. or i.p.; sP and P rats	24-hr F-C, acquisition, on-going, relapse; limited access; operant	(a) Blocking 5-HT <sub>3</sub> receptors effectively reduced EtOH drinking under 24-hr F-C conditions during acquisition and on-going drinking; (b) 5-HT <sub>3</sub> receptor antagonists are less effective with 24-hr F-C relapse drinking; (c) under scheduled limited access (1 or 2 hr) 5-HT <sub>3</sub> antagonists were ineffective in reducing EtOH intake, unless the limited access period was randomly presented at different times during the night cycle; (d) the results indicate that 5-HT <sub>3</sub> receptors have a significant role in regulating EtOH intake when certain anticipatory conditioning factors are absent	Fadda <i>et al.</i> , 1991; McKinzie <i>et al.</i> , 1998, 2000; Rodd-Henricks <i>et al.</i> , 2000
5-HT <sub>4</sub> antagonist: GR113808; s.c.; rats	2-hr limited access; 10% EtOH	Blocking 5-HT <sub>4</sub> receptors dose-dependently reduced EtOH intake without altering water or food intakes, suggesting that 5-HT <sub>4</sub> receptors have a significant role in maintaining alcohol drinking	Panocka <i>et al.</i> , 1995

*Abbreviations:* P, alcohol-preferring; NP, alcohol-non-preferring; HAD, high-alcohol-drinking; LAD, low-alcohol-drinking; 5,7-DHT, 5,7-dihydroxytryptamine; 8-OH-DPAT, 8-hydroxy-2-(di-*n*-propylamino)-tetralin; MRN, median raphe nucleus; DRN, dorsal raphe nucleus; RN, raphe nuclei; F-C, free-choice; FR, fixed ratio; EtOH, ethanol; s.c., subcutaneous; i.p. intraperitoneal; i.g., intragastric; AA, Alko Alcohol; FH, Fawn Hooded; sP, Sardinian alcohol-preferring; sNP, Sardinian alcohol-non-preferring.

Sprague-Dawley rats may not consume sufficient EtOH to produce measurable BACs; therefore, there may not be a CNS effect of EtOH that can be influenced by removing CNS 5-HT modulation. In addition, the effects of 5,7-DHT lesions occurs over several days, and there may be compensatory mechanism developing during this time. Although the intakes of Wistar rats are low (Tomkins *et al.*, 1994a, 1994b), these rats appear to consume sufficient EtOH in the limited access period to produce measurable BACs; therefore, in this case there may be a CNS effect of EtOH, which can be modulated by manipulating 5-HT neuronal activity.

Selective receptor agonists or antagonists have been used to explore the involvement of certain 5-HT receptor subtypes in regulating EtOH intake (Table 4). Systemic administration of low doses of 8-OH-DPAT, a 5-HT<sub>1A</sub> receptor agonist, increased EtOH intake (Tomkins *et al.*, 1994b; McKenzie-Quirk and Miczek, 2003), presumably through its action at cell body 5-HT<sub>1A</sub> autoreceptors. However, higher doses of the 5-HT<sub>1A</sub> receptor agonist reduced EtOH intake (McBride *et al.*, 1990; Svensson *et al.*, 1993; Tomkins *et al.*, 1994b; Wilson *et al.*, 1996; McKenzie-Quirk and Miczek, 2003), presumably through its additional actions at postsynaptic 5-HT<sub>1A</sub> receptors. In contrast to the effects of an agonist, systemic

administration of a 5-HT<sub>1A</sub> receptor antagonist had little effect on alcohol intake (Ciccocioppo *et al.*, 1997; Tomkins and O'Neill, 2000). Similarly, activating 5-HT<sub>1B</sub> receptors reduces EtOH intake, whereas administration of a 5-HT<sub>1B</sub> receptor antagonist had little effect on EtOH intake (Tomkins and O'Neill, 2000). Overall, the results support the idea that reduced 5-HT neuronal activity increased EtOH intake, and that activation of postsynaptic 5-HT<sub>1A</sub> and 5-HT<sub>1B</sub> receptors can inhibit EtOH intake, although these receptors do not appear to be actively involved in modulating ongoing EtOH drinking.

The involvement of 5-HT<sub>2A</sub> and 5-HT<sub>2C</sub> receptors in regulating alcohol drinking has also been studied (Table 4). Overstreet *et al.* (1997) examined the effects of 5-HT<sub>2A</sub> receptor antagonists on EtOH, water and food intake of P, Alko-Alcohol (AA) and Fawn Hooded (FH) rats, all high-alcohol-drinking rats. The two 5-HT<sub>2A</sub> receptor antagonists tested reduced EtOH, total fluid and food intakes, and produced conditioned taste aversion (Table 4), suggesting that these receptors are involved in modulating consummatory behaviors in general. The effects of 5-HT<sub>2C</sub> receptors have been studied under operant conditions (Tomkins *et al.*, 2002); systemic administration of an agonist reduced responding, whereas injection of an antagonist increased responding (Table 4).

These results suggest that 5-HT<sub>2C</sub> receptors can modulate EtOH drinking and be involved in a mechanism for limiting the amount of EtOH consumed.

The involvement of 5-HT<sub>3</sub> receptors in regulating alcohol drinking has received considerable attention (see overview by McBride *et al.*, 2004) because of the evidence that EtOH can potentiate the excitatory actions of 5-HT at this receptor (Lovinger and White, 1991; Lovinger *et al.*, 2000). However, despite the documented action of EtOH at the 5-HT<sub>3</sub> receptor, the effects of 5-HT<sub>3</sub> receptor antagonists depend upon the alcohol drinking conditions (Table 4). Fadda *et al.* (1991) demonstrated that i.p. administration of the 5-HT<sub>3</sub> receptor antagonist MDL 72222 suppressed 24-hour free-choice drinking in the Sardinian alcohol-preferring (sP) rats. In agreement with this latter study, Rodd-Henricks *et al.* (2000) reported that systemic administration of 5-HT<sub>3</sub> antagonists reduced 24-hour free-choice EtOH intake of P rats under acquisition or maintenance EtOH drinking conditions. However, these latter investigators reported that these same 5-HT<sub>3</sub> receptor antagonists were much less effective under relapse conditions in reducing EtOH intake. McKinzie *et al.* (1998) reported that MDL72222 and ICS 205-930, well-established 5-HT<sub>3</sub> receptor antagonists, reduced EtOH intake of P rats under 24-hour free-choice conditions, but the same doses of the antagonists were not effective in reducing EtOH intake of P rats under 2- or 4-hour limited access conditions, unless the limited EtOH access (only the 2-hour period tested) period was randomly given. In a follow-up study, McKinzie *et al.* (2000), using operant scheduled access, reported that systemic administration of MDL 72222 had no effect on operant responding for EtOH by P rats when the operant session was scheduled at the same time each day, but the antagonist was effective at reducing responding on the EtOH lever if the 1-hour operant session was randomly given each day. The results of the latter two studies suggest that 5-HT<sub>3</sub> receptors are actively involved in regulating EtOH intake, but conditioning factors produce neuronal alterations that reduce the effectiveness of the 5-HT<sub>3</sub> receptor antagonists.

The effects of the s.c. administration of the 5-HT<sub>4</sub> antagonist GR113808 were tested under 2-hour limited access conditions (Table 4). The results of this study (Panocka *et al.*, 1995) indicate that inhibiting 5-HT<sub>4</sub> receptors dose-dependently reduced EtOH drinking without altering water or food intakes, suggesting that 5-HT<sub>4</sub> receptors have a significant role in maintaining alcohol drinking.

Overall, the results suggest that, in general, lower functioning of the 5-HT systems originating from the MRN and DRN is associated with higher alcohol drinking, and that activation of postsynaptic 5-HT<sub>1A</sub>, 5-HT<sub>1B</sub> and 5-HT<sub>2C</sub> receptors has a negative effect on EtOH intake. On the other hand, there is evidence supporting a positive influ-

ence for activation of 5-HT<sub>3</sub> and 5-HT<sub>4</sub> receptors on EtOH intakes. Therefore, it is possible that activation of certain 5-HT pathways involving 5-HT<sub>3</sub> and 5-HT<sub>4</sub> synapses would promote alcohol intake, whereas activation of 5-HT pathways involving 5-HT<sub>1A</sub>, 5-HT<sub>1B</sub> and 5-HT<sub>2C</sub> postsynaptic receptors would reduce EtOH intake.

## Summary/conclusions

In general, 5-HT appears to have a negative modulatory effect on the brain reward system, in that general activation of 5-HT MRN and DRN systems reduces reward, whereas reducing the function of these 5-HT systems increases reward, as measured in studies of ICSS of the LH and MFB place conditioning experiments, and CR experiments. Similarly, low function of the 5-HT system appears to be associated with the rewarding effects of alcohol, as indicated by effects on alcohol drinking behavior. Although inhibitory effects appear to be the main effect of the 5-HT systems on reward, there is also evidence that some synaptic pathways involving certain subtypes of 5-HT receptors may promote reinforcing effects. In summary, the MRN and DRN 5-HT neuronal systems have important roles in modulating brain reward.

# Role of Central Serotonin in Impulsivity and Compulsivity: Comparative Studies in Experimental Animals and Humans

Trevor W. Robbins\* and Molly J. Crockett\*

*Department of Experimental Psychology and Behavioural and Clinical Neuroscience Institute,  
University of Cambridge, Cambridge, UK*

**Abstract:** The involvement of serotonin in impulsivity (the tendency to respond prematurely) and compulsivity (the tendency to perseverate) is reviewed from the joint perspective of animal and human studies. Evidence is provided to support a role for serotonin in some forms of impulsivity, but not others, and in compulsivity. However, it is difficult to accommodate these roles into a common scheme implicating behavioral inhibition. The implications for neuropsychiatric disorders such as obsessive-compulsive disorder are considered.

**Keywords:** impulsivity, compulsivity, behavioral inhibition, striatum, prefrontal cortex, ADHD, obsessive-compulsive disorder.

## Introduction

Serotonin (or 5-hydroxytryptamine, 5-HT) has been implicated in many behavioral and physiological functions, which is not surprising, given the diverse ramification of central 5-HT neurons and the existence of at least 14 distinct 5-HT receptors. However, the unitary functions most often attributed to this system have been those of aversive motivation (Wise *et al.*, 1972; Deakin and Graeff, 1991) and behavioral inhibition (Gray, 1982; Soubrié, 1986). The latter is most relevant to theories of impulsivity and compulsivity, although 5-HT may also be linked with these constructs through its possible role in aversive motivation. This chapter will summarize the research especially relevant to the impulsivity/compulsivity theme, and will draw on work performed in this laboratory as well as others, in both experimental animals and human volunteers.

As Gray (1982) himself realized, there are clear reciprocal relationships between apparently opponent appetitive and aversive systems, whereby the omission of an expected positive reinforcer (or 'reward') has aversive consequences, and the omission or postponement of an aversive reinforcer is perceived in a positive light.

Whether these two contingencies actually are equivalent to receiving an aversive or appetitive reinforcer, respectively, seems somewhat dubious, although they may share some generalized emotional congruence. There is a similar conundrum in terms of the relationship between aversive motivation and inhibition: a punishing contingency normally results in the suppression of appetitive behavior, whereas the unconditioned response for a rodent to a pavlovian aversive reinforcer is to freeze. So a manipulation of the 5-HT system which reduces the unconditioned response to an aversive reinforcer (e.g., freezing in rodents) generally *also* causes increases in overall motor output, or 'behavioral disinhibition'. The question is, which of these roles ascribed to 5-HT is primary: inhibition or aversiveness? A further complication has been the fact that different aspects of aversiveness also implicate 5-HT; thus Deakin and Graeff (1991) pointed out that increasing levels of 5-HT transmission are associated with anxiety, and decreasing levels with depression. Throughout this chapter we will observe how seemingly opposite functional effects can follow superficially similar manipulations of 5-HT neurotransmission, in a manner that almost appears bound to confound any attempt to assign a unitary function to this system. These paradoxes, however, serve to strengthen our understanding of the 5-HT system, and how its operation may depend on subtle contextual demands.

## 5-HT and impulsivity

Impulsivity is generally defined as the tendency to respond prematurely without adequate foresight, sometimes with adverse consequences. This definition conceals a number of possibly distinct aspects of impulsivity which may each implicate an inhibitory process – for example, inhibition of an action or response or inhibition of the salience of an appetitive goal. Moreover, an impulsive decision can result from an altered criterion in terms of perceptual evidence sampled, or from altered processing of reinforcement contingencies. In our work with rats we employ three tests of impulsivity that capture these distinct forms; premature responding in a five-choice serial reaction time task; stop-signal inhibition; and temporal discounting of reward. These tests reveal different neural and neurochemical substrates for these distinct forms

of impulsivity, although with some overlap sufficient to encourage the notion of a unitary construct (Robinson *et al.*, 2008a; but see also Winstanley *et al.*, 2004a).

### *Impulsivity in the five-choice serial reaction time task (5-CSRTT)*

The 5-CSRTT is a test paradigm in which rats are trained to detect brief visual targets presented randomly in five locations to earn food (Figure 1). Rats have a propensity to respond prematurely in this task, particularly as the duration of the visual target is reduced, although this behavior is punished by time-out from positive reinforcement. This tendency is quite variable between individuals, with a small proportion of rats exhibiting high degrees of impulsive responding, even after extended training.

**Figure 1** Contrasting effects of the 5-HT<sub>2A</sub> receptor antagonist M100907 and the 5-HT<sub>2C</sub> receptor antagonist SB242084 on premature responding in the 5-choice serial reaction time task in rats with either forebrain 5-HT depletion from the forebrain or the control treatment (sham surgery). The five-choice paradigm is also shown. The figures are reproduced from Winstanley *et al.* (2004b) and Robbins (2002), by permission of the publishers (Springer-Verlag).

An early experiment showed that profound (>85 percent loss in most forebrain regions assayed, including neocortex and striatum) depletion of forebrain 5-HT induced by intraventricular administration of the selective neurotoxin 5,7 dihydroxytryptamine (5,7-DHT) produced significant and essentially permanent increases in premature responding (Harrison *et al.*, 1997a). Further experiments targeting separately the dorsal and medial raphe nuclei indicated that lesions of the dorsal nucleus, which projects preferentially to the neocortex and striatum, produced higher levels of impulsive responding, sometimes in conjunction with improved accuracy (Harrison *et al.*, 1997b).

The increase in premature responses in the 5-CSRTT following intraventricular 5,7-DHT was replicated and extended by Winstanley *et al.* (2004b), who also demonstrated that the effect was ameliorated to some extent by systemic administration of M100907, the 5-HT<sub>2A</sub> receptor antagonist. However, the suppression of premature responses was enhanced by lower doses of M100907 in sham-operated control rats (see Figure 1). By contrast, systemic administration of the 5-HT<sub>2C</sub> receptor antagonist SB242084 exacerbated impulsivity produced by the 5-HT depletion, although again the exacerbation was obtained at lower doses in controls (Figure 1). This different pattern of effects of the 5-HT<sub>2A</sub> and 5-HT<sub>2C</sub> receptor antagonists (Figure 2) has since been reproduced following intracerebral administration into the nucleus accumbens (Robinson *et al.*, 2008a), a structure known to be implicated in impulsivity on the 5-CSRTT, and possibly reflecting an interaction between 5-HT and mesolimbic dopamine (DA) (Berg *et al.*, 2008). These contrasting

effects of 5-HT<sub>2A</sub> and 5-HT<sub>2C</sub> agents are consistent with other data on effects of 5-HT<sub>2A</sub> and 5-HT<sub>2C</sub> agonists on impulsive responding when administered systemically (Koskinen *et al.*, 2000; Fletcher *et al.*, 2007; Navarra *et al.*, 2008). The opposite effects of the 5-HT<sub>2A</sub> and 5-HT<sub>2C</sub> antagonist are perhaps surprising in view of their structural similarities, and commonalities in their effects on secondary messengers (Conn and Sanders-Bush, 1987), but presumably reflect their differential involvement in neuronal circuitry modulated by serotonin (see, for example, Pompeiano *et al.*, 1994; Berg *et al.*, 2008; Calcagno *et al.*, 2009).

Whereas ventral striatal 5-HT is implicated in impulsive responding induced on the 5-CSRTT, the involvement of cortical 5-HT is a little less clear. Previous work has established that the infralimbic (IL-) or ventromedial prefrontal cortex (PFC) is particularly implicated in the control of impulsivity, but not accuracy, of responding in the 5-CSRTT (Chudasama *et al.*, 2003; Murphy *et al.*, 2005). Dalley *et al.* (2002) actually found that the more highly impulsive rats tended to have *higher* levels of 5-HT in the medial prefrontal cortex (mPFC) as measured using *in vivo* microdialysis, seemingly in contradiction of a role for 5-HT in behavioral inhibition. This putative increase in mPFC 5-HT neurotransmission was apparently supported by findings that intra-mPFC infusions of ketanserin (a mixed 5-HT<sub>2A/C</sub> antagonist; Passetti *et al.*, 2003) and the more selective 5-HT<sub>2A</sub> receptor antagonist M100907 (Winstanley *et al.*, 2003) reduced premature responses on the 5-CSRTT. However, these effects were only obtained in modified versions of the task when the duration of the visual targets was reduced. With standard task parameters, Robinson *et al.* (2008b) found no effect of either M100907 or the 5-HT<sub>2C</sub> receptor antagonist SB242084 when infused intra-mPFC. However, Carli *et al.* (2006) found that intra-mPFC M100907 did antagonize the increased premature responses induced by intra-mPFC infusions of the NMDA receptor antagonist CPP, consistent with the possibility of the modulation of glutamate responses by the 5-HT<sub>2A</sub> receptor in this region. This blocking effect is also consistent with the fact that premature responses had a high baseline in the study by Winstanley *et al.* (2003), but a low one in the experiment of Robinson *et al.* (2008b). Thus, it appears that the 5-HT<sub>2A</sub> receptor does modulate impulsivity within the mPFC under some circumstances, consistent with the high density of 5-HT<sub>2A</sub> receptors in this region (Santana *et al.*, 2004). Recent evidence suggests that there is also a balance between the influence on pyramidal cell output of 5-HT<sub>2A</sub> and 5-HT<sub>2C</sub> receptor activity in this region (Calcagno *et al.*, 2009). Thus, in parallel with the enhanced impulsivity elicited by intra-mPFC CPP and

its reversal by M100907, the enhanced glutamate release following intra-mPFC CPP by M100907 was blocked by concurrent administration of a 5-HT<sub>2C</sub> receptor antagonist. Furthermore, Calcagno *et al.* (2009) have found that the enhanced impulsivity produced by intra-IL-PFC CPP can be blocked by a 5-HT<sub>2C</sub> agonist. The functional interaction between 5-HT<sub>2A</sub> and 5-HT<sub>2C</sub> receptors may be mediated by their neuronal effects at pyramidal cells, and on parvalbumin-containing GABA neurons, respectively (see Liu *et al.*, 2007; Calcagno *et al.*, 2009).

This series of studies has shown that the involvement of 5-HT in one form of impulsivity, premature responding in the 5-CSRTT, is quite complex, with behavioral disinhibition certainly being the outcome of global forebrain 5-HT loss. However, there is evidence that the effects of two subtypes of the 5-HT<sub>2</sub> receptor are reciprocally involved in the regulation of impulsivity. This reciprocity is also expressed within the nucleus accumbens and the mPFC, as well as other possible neural sites. A further question is, what form of impulsivity is captured by the premature responding measure in the 5-CSRTT? It quite possibly reflects perceptual and motivational, as well as motor, aspects.

### ***Response inhibition: stop signal inhibition and Go/NoGo paradigms***

As will be seen below, there are several ways of inferring effects of 5-HT manipulations on motor inhibition, which lead to a surprising, but informative, conclusion (Table 1). In this section, we also compare studies performed in the same paradigm with human as well as animal subjects. Although it is feasible to manipulate 5-HT function in humans, there is a relative dearth of means for doing this. Some of the most often used methods are shown in Box 1.

### ***Stop-signal reaction time task (SSRTT)***

Logan's stop-signal reaction time task was devised originally for human subjects with applications especially to patients with attention deficit hyperactivity disorder (ADHD) (Logan *et al.*, 1984). Simply speaking, the SSRTT measures the speed with which an initiated action can be cancelled or inhibited (see Eagle and Robbins, 2008a, for a full theoretical description). Recently, it has

### Common methods for manipulating 5-HT in humans

#### *Acute tryptophan depletion (ATD)*

ATD induces a transient 5-HT deficit in the CNS (Carpenter *et al.*, 1998). In the ATD procedure, participants ingest an amino acid load via a drink that contains all of the large neutral amino acids (LNAAs) except for tryptophan, which is the chemical precursor of 5-HT. Tryptophan competes with other LNAAs for access via the blood-brain barrier through the LNAA transporter. Lowering the tryptophan:LNAA ratio almost completely halts tryptophan transport into the brain. Microdialysis in rats has shown that ATD attenuates 5-HT release in frontal cortex and midbrain raphe nuclei (Bel and Artigas, 1996). In human subjects, plasma and CSF tryptophan levels reach nadir 5 hours after the administration of the amino acid mixture (Carpenter *et al.*, 1998).

#### *Tryptophan supplementation and loading*

Tryptophan supplementation and loading are thought to enhance 5-HT function by increasing availability of tryptophan. Tryptophan loading involves a similar procedure to ATD, but the amino acid load contains a large amount of tryptophan. In the tryptophan supplementation procedure, participants take daily supplements of tryptophan in tablet form, often for several weeks. Both procedures increase tryptophan availability to levels that saturate tryptophan hydroxylase, the rate-limiting enzyme that converts tryptophan to 5-HT (Young and Gauthier, 1981).

#### *Acute vs chronic SSRI administration*

Selective serotonin reuptake inhibitors (SSRIs) increase the concentration of 5-HT in the synapse by blocking its presynaptic reuptake. They do so by blocking the presynaptic active transport mechanism in the 5-HT transporter (5-HTT). Consequently, the action of 5-HT on postsynaptic receptors is enhanced (Spinks and Spinks, 2002). The onset of an SSRI's clinical effects can be delayed 1 or 2 weeks from the start of treatment (Taylor *et al.*, 2006), despite the fact that these drugs inhibit 5-HT reuptake within hours of administration (Bymaster *et al.*, 2002). The underlying mechanisms of this effect are presumed to involve the presynaptic 5-HT<sub>1A</sub> autoreceptors. When released 5-HT activates these receptors, potassium channels are opened, leading to hyperpolarization of the cell and inhibition of cell firing, which results in decreased 5-HT release (Blair *et al.*, 1998).

SSRI-induced increases in synaptic 5-HT are thus countered by negative feedback on serotonergic release caused by 5-HT binding to autoreceptors, which may explain why SSRIs do not show clinical effects immediately after administration. The effects of acute administration of SSRIs may therefore mirror those of serotonin depletions, such as ATD (Carpenter *et al.*, 1998). The lower acute doses used in research in human volunteers are particularly likely to have autoreceptor effects to decrease extracellular 5-HT levels. Chronic administration of SSRIs, however, is thought to enhance serotonergic neurotransmission, as autoreceptors desensitize with repeated drug administration and firing of 5-HT neurons is restored (Blair *et al.*, 1998).

#### *Pharmacological fMRI*

All of the above methods can be combined with functional magnetic resonance imaging (fMRI) to probe the effects of altered 5-HT neurotransmission on the neural correlates of behavior. Interpreting the effects of 5-HT manipulations on neural activity is not straightforward, however, and must be approached with caution when the manipulation does not produce effects on behavior. When 5-HT manipulation does affect fMRI results, it is not yet possible to determine the underlying mechanism; for example, enhanced neural activity could reflect increased neurotransmission due to greater efficiency, or the need to recruit more neurons due to impaired efficiency (Anderson *et al.*, 2008).

proven possible to configure this task appropriately for monkeys and rodents (Eagle and Robbins, 2003; Eagle *et al.*, 2008a) allowing for comparisons to be made across species. Performance in the SSRTT appears to involve structures other than the nucleus accumbens in the rat; in fact, an orbitofrontal cortex (OFC)–medial striatal–subthalamic nucleus system has been implicated, which may overlap with the neural network engaged during performance of the task in an fMRI paradigm in humans (Aron and Poldrack, 2006).

So far, manipulations of the central 5-HT system have shown few effects on performance of the SSRTT. The selective serotonin reuptake inhibitor (SSRI) citalopram has no effect on performance in rats (Eagle *et al.*, 2008a; Bari *et al.*, 2009) on acute administration. More strikingly, global forebrain 5-HT depletion in rats also has no effect on the SSRTT, which contrasts markedly with its effects to induce impulsive responding in the 5-CSRTT or in the Go/NoGo paradigm (Eagle *et al.*, 2008b). However,

if the period for which a response has to be inhibited on the SSRTT is prolonged, then 5-HT depletion in the rat does produce behavioral disinhibition; there is a deficit in 'waiting' but not 'stopping' itself (Eagle *et al.*, 2008b).

The effects of 5-HT manipulations in humans on SSRTT performance for the most part parallel the findings in rats, with a few complications (Table 1). Acute tryptophan depletion (ATD) had no effect on response inhibition in the SSRTT (Clark *et al.*, 2005), and neither did acute administration of the SSRI citalopram (Chamberlain *et al.*, 2006). However, another study found that ATD impaired SSRTT performance in males with a family history of alcoholism, but *improved* performance in males without a family history of alcoholism (Crean *et al.*, 2002). Whether these more complex findings reflect the release by ATD of contrasting underlying individual tendencies, or differential individual responses to the ATD procedure, remains unclear.

#### *Go/NoGo discrimination*

Go/NoGo discrimination is another paradigm used to measure response inhibition. In this task, inhibition has to be exerted in the response selection phase, whereas in the SSRTT, response selection has already occurred but the performance of the response has to be curtailed. Considerable evidence links a reduction of 5-HT to behavioral disinhibition in Go/NoGo paradigms, including classical findings reviewed by Soubrié (1986). The interpretation of such data is generally along the lines that impaired 5-HT function results in a reduction of response inhibition, and hence the increase in non-reinforced or even punished NoGo responding. An alternative account is that the aversive consequences of responding on NoGo trials are reduced by 5-HT depletion. The latter hypothesis is difficult to refute, but we have attempted to address it by studying in parallel two similar tasks. In the first of these, acquiring a Go/NoGo discrimination depended on responding differentially to a fast-flashing or slow-flashing visual stimulus (counterbalanced across rats). Global 5-HT depletion actually completely prevented the acquisition of this discrimination, as the depleted rats failed to inhibit responding to the NoGo stimulus (regardless of whether it was fast or slow), although withholding the response, like performing the Go response, was symmetrically reinforced with food. If rats were pre-trained to solve the discrimination, 5-HT depletion impaired performance by inducing inappropriate responding on NoGo trials – though not to the extent of the complete behavioral disinhibition observed during acquisition (Harrison *et al.*, 1999).

In a complementary experiment, rats were trained in a conditional Go/Go discrimination based on similar fast

and slow-flashing visual stimuli. In this situation, 5-HT depletion actually *improved* acquisition of the discrimination. Therefore, it is difficult to argue that 5-HT depletion reduced the impact of reward omission, as this would presumably also have impaired trial-and-error discrimination learning. The more parsimonious hypothesis is that it impaired response inhibition in the Go/NoGo procedure, but this deficit was largely irrelevant to the Go/Go task (Ward *et al.*, 1999). Note that these findings also approximate the effect of forebrain 5-HT loss on performance on the 5-CSRTT, where again premature responding was enhanced, but visual discrimination was unaffected or even enhanced (Harrison *et al.*, 1997a, 1997b).

In humans, the effects of 5-HT manipulations on Go/NoGo discrimination are more complex. Paralleling the findings in rats, Walderhaug *et al.* (2002) reported increased impulsivity or disinhibition following ATD in a continuous performance task requiring Go/NoGo discrimination. However, several other findings are less straightforward (Table 1). A later study using the same continuous performance task showed that ATD increased impulsivity in males, but *decreased* impulsivity in females (Walderhaug *et al.*, 2007). LeMarquand *et al.* (1999) found that ATD increased impulsive responses in the Go/NoGo task in males with a family history of alcoholism, but not in males without a family history of alcoholism. Two more recent studies found no effect of ATD on Go/NoGo discrimination in male and female healthy volunteers (Evers *et al.*, 2006; Crockett *et al.*, 2008). Furthermore, it could be argued that performance on the Stroop task involves inhibitory control in the response selection phase, and thus taps into the same mechanisms of the Go/NoGo task. However, two studies have found that ATD *enhances* performance on the Stroop task (Evers *et al.*, 2006; Scholes *et al.*, 2006). Thus, in humans the effects of ATD on Go/NoGo discrimination are not straightforward and appear to depend to a certain extent on individual vulnerability factors, such as gender or family history of psychopathology.

Researchers have used fMRI to investigate whether 5-HT manipulations modulate brain activity during Go/NoGo discrimination. One study found that ATD attenuated activity in the right inferior frontal gyrus (rIFG) during the Go/NoGo task (Rubia *et al.*, 2005); another study reported no effect of ATD on neural activity during the Go/NoGo task (Evers *et al.*, 2006). A third study found enhanced rIFG activity during the Go/NoGo task following acute pre-treatment with the SSRI citalopram (Del-Ben *et al.*, 2005). These findings provide some evidence for serotonergic modulation of the neural correlates of response inhibition, but it is important to note that none of these studies found effects of ATD on behavioral measures of response inhibition.

One potential explanation for these mixed results is that the behavioral tasks typically used to measure response inhibition in humans are non-reinforced: subjects do not receive rewarding or punishing feedback for their responses. But the 5-HT-inhibition hypothesis was based on animal work that employed reinforced tasks (Soubrié, 1986). This suggests that the results obtained in animal studies could be due to the involvement of 5-HT in reinforcement processing. 5-HT has indeed been linked with behavioral and neural indices of reinforcement processing in a variety of paradigms.

In summary, 5-HT manipulations have strikingly different effects on performance in two different tasks designed to measure response (including motor) inhibition. When response selection is involved prior to response initiation, 5-HT appears to have an important role in suppressing impulsive NoGo responding. This parallels the effects of 5-HT depletion on premature responding in the 5-CSRTT. In contrast, after a response has been initiated, 5-HT appears to no longer play a role in motor inhibition. Behavioral manipulations suggest that the predominant effect of 5-HT loss is to induce deficits in the capacity to wait rather than stop (Table 1). Clearly, this distinction goes beyond a simple theory of 5-HT involvement in behavioral inhibition; response inhibition may be involved in both circumstances, but the 5-HT system appears to be implicated only in one of them.

### ***Temporal discounting of reward: impulsive choice***

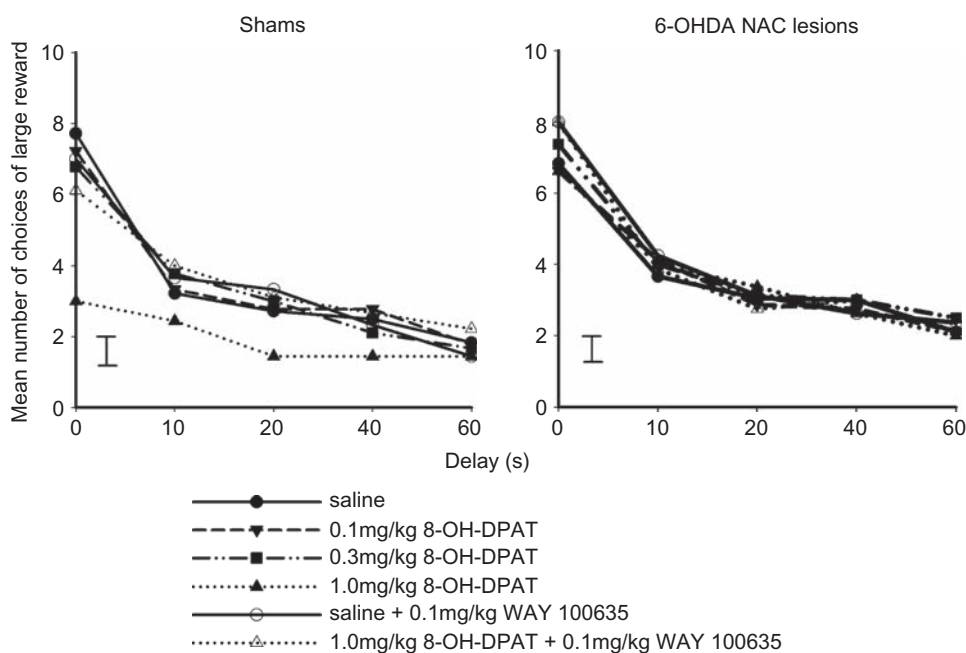

This refers to the choice between small immediate rewards and large delayed ones – an elemental form of decision-making. Other versions of temporal discounting or ‘inter-temporal choice’ may pit the choice between small immediate rewards and avoidance of large delayed punishment, as may occur in several decisions involving personal health choices, such as those involved in addiction. Previous work has suggested that down-regulating 5-HT function in rats by combined dorsal and median raphe 5,7-DHT increases impulsive choice (see, for example, Mobini *et al.*, 2000). However, using the same intraventricular treatment with 5,7-DHT as previously, we found no effect on temporal discounting in an operant procedure in which hungry rats responded for either immediate single food pellets, or for four pellets presented at varying delays culminating in 60 s. The resulting choice behavior could readily be fit by a hyperbolic discounting function, but there was no effect on temporal discounting following profound forebrain 5-HT loss. However, such 5-HT depletion did have effects on temporal discounting affected by systemic d-amphetamine. The latter treatment (repeated three times) dose-dependently *reduced* impulsive

choice, inducing rats to respond on the lever associated with the large, delayed reward. This effect was only significant, however, for those rats with initially steep discounting functions – i.e., in rats showing impulsive choice. Intriguingly, given that d-amphetamine is an indirect catecholamine agonist, its effects to reduce impulsive choice were blocked by 5-HT depletion. The effects of d-amphetamine could also be blocked by the mixed D1/D2 receptor blocker  $\alpha$ -flupenthixol, but only in 5-HT-depleted rats, suggesting that they were mediated by an *interaction* between DA and 5-HT systems. Further evidence for such an interaction comes from the fact that mesolimbic DA depletion achieved by intra-accumbens 6-hydroxydopamine failed by itself to block the anti-impulsive effect of d-amphetamine. Furthermore, the 5-HT<sub>1A</sub> receptor antagonist WAY 100635 enhanced the action of d-amphetamine to reduce impulsive choice (Winstanley *et al.*, 2005).

The most likely site of action for these interactions is the nucleus accumbens, core region, as excitotoxic lesions of this structure have been found to cause impulsive choice in the same paradigm (Cardinal *et al.*, 2001). 5-HT<sub>1A</sub> receptors are known to be located on DA cells in the ventral tegmental area that projects to the nucleus accumbens (as well as within the nucleus accumbens itself). Acute, systemic treatment with the 5-HT<sub>1A</sub> agonist 8-OH-DPAT elicits strong impulsive choice, an effect which is blocked by a 5-HT<sub>1A</sub> receptor antagonist, but which is not blocked by 5-HT depletion, suggesting that it is postsynaptic in origin. In contrast, such impulsivity is blocked by 6-OHDA lesions of the nucleus accumbens, which deplete dopamine there (Figure 3). At the dose used to induce impulsive choice, 8-OH-DPAT may thus induce impulsive responding by facilitating release of DA in the nucleus accumbens. These findings again highlight the intimate interactions of DA and 5-HT in the control of impulsive behavior.

An *in vivo* microdialysis study of delayed discounting by Winstanley *et al.* (2006) found elevated extracellular 5-HT within the mPFC specifically related to an instrumental choice condition, independent of the effects in separate groups of passive reward presentation, or of instrumental behavior without choice. This contrasted with findings for DA in mPFC which was elevated following passive reward presentation or during instrumental behavior, as well as during impulsive choice. Within the OFC, however, DA was more reliably associated with impulsive choice behavior.

The relationship between low or impaired 5-HT and ‘impulsive’ inter-temporal choice described above has been extended to humans. An early study found no effect of ATD on a temporal discounting of reward task (Crean *et al.*, 2002). The authors suggested that the

**Figure 3** Hyperbolic temporal discounting in the rat as affected by an acute dose of the 5-HT<sub>1A</sub> receptor agonist 8-OHDPAT. The steeper discounting (i.e., impulsive responding) produced by this drug is abolished by prior dopamine depletion in the nucleus accumbens, which by itself has no effect. Reproduced from Winstanley *et al.* (2005).

inter-temporal choice task, which was questionnaire-based, was perhaps insufficiently sensitive to detect effects of altered 5-HT. A later study used an inter-temporal choice task with experiential delays (as are used in the animal studies reviewed above), and found that ATD increased choices for the smaller, sooner reward, paralleling at least some of the complex findings from rat studies (Schweighofer *et al.*, 2008). An fMRI study using the same task suggested that ATD increases impulsive inter-temporal choice by enhancing activity in the ventral striatum during short-term reward prediction (Tanaka *et al.*, 2007). In the same study, augmenting 5-HT function with tryptophan supplementation enhanced activity in the dorsal striatum during long-term reward prediction. It will be interesting to see if these data can be confirmed in animal studies.

In summary, as in the case of the premature responding in the 5-CSRTT, impulsive behavior was modulated by 5-HT mechanisms. Although the relevant brain regions still have not been fully elucidated, available data again point to a cortico-striatal mediation, as well as to complex interactions with dopamine, probably at both a cortical and striatal level. Evidence for a strong version of the 5-HT hypothesis of behavioral inhibition is lacking. Instead, the effects of 5-HT manipulations on impulsive choice appear to be more related to altered representations of instrumental outcomes.

### 5-HT and decision-making cognition

Representing reward and punishment contingencies of decision outcomes is of critical importance in gambling and risk-taking tasks, where subjects must weigh the relative potential costs and benefits of different response options. An early study with the Cambridge Gamble Task found that ATD reduced choices for the most probable outcome (i.e., the outcome with the highest expected value) (Rogers *et al.*, 1999a), suggesting that 5-HT is important for integrating information about the value and likelihood of choice outcomes. However, a subsequent study using the same task found the opposite effect; ATD *increased* choices for the most probable outcome (Talbot *et al.*, 2006). Either way, these results imply that 5-HT modulates the influence of reinforcement contingencies on choice. This process may be supported by a serotonergic modulation of the representation of reward magnitudes. Supporting this view, Rogers *et al.* (2003) reported that ATD reduced discrimination between magnitudes of expected rewards associated with different choice outcomes in a risk-taking task. Enhancing 5-HT function with tryptophan supplementation did not improve reward discrimination, however. Instead, tryptophan supplementation reduced framing effects in the loss domain – following tryptophan supplementation; subjects chose certain small losses over uncertain larger losses significantly more

frequently than the placebo group (Murphy *et al.*, 2009). The authors interpreted this finding as evidence that tryptophan supplementation reduced loss aversion, which fits with other work linking reduced 5-HT to enhanced punishment processing. The neural correlates of these behavioral effects remain unclear, and it is still not well understood how 5-HT modulates the impact of expected rewards and punishments on decision-making cognition.

Social decision-making also involves weighing short-term desires against long-term goals (e.g., compliance with social norms). To investigate decision-making cognition in social contexts, researchers typically set up games with multiple players. In these games, subjects must decide whether or not to cooperate with, trust, or retaliate against their partner. Social decision-making has been linked to 5-HT function. Chronic (2-week) pre-treatment with the SSRI citalopram enhanced cooperative decisions in the Prisoner's Dilemma game (Tse and Bond, 2002); ATD had the opposite effect (Wood *et al.*, 2006). In the Ultimatum Game, ATD increased retaliation against unfair treatment (Crockett *et al.*, 2008). Notably, the effects of ATD on Ultimatum Game decision-making mirror the effects of lesions to the ventromedial prefrontal cortex (Koenigs and Tranel, 2007), suggesting a role for 5-HT in modulating decision-making cognition in this brain region.

### 5-HT and compulsivity

A clinical distinction is often made between impulsivity and compulsivity (Hollander and Rosen, 2000). In the latter case, we may define this as the inappropriate perseveration of responding, despite adverse consequences. Whereas ADHD is perhaps the most characteristic clinical example of impulsivity, obsessive-compulsive disorder is the paradigmatic example of compulsivity. Like impulsivity, compulsivity can be measured in a variety of ways and is probably not a unitary construct. For example, compulsivity can be measured in some sense by a failure to stop responding, and so the SSRTT may have an ambiguous position in this respect. However, perseveration in tasks in which altered reinforcement contingencies dictate that it is appropriate to switch responding are generally used to characterize compulsivity. The simplest version of this is extinction (reinforcement omission); increased resistance to extinction can be taken as an example of perseverative responding likely to involve inhibitory processes, given that modern conceptions of extinction suggest that it involves an active inhibitory process that suppresses stimulus–reward or action–outcome contingencies. Another measure is provided by discrimination reversal learning, in which previous associations between one stimulus and a rewarding outcome, and the other and reward omission

or punishment, are reversed, so that the animal has to adapt appropriately to the altered environmental situation. Failure to reverse may in part occur because of a failure to learn the new stimulus–response associations; this learning is prevented if the animal persists in responding to the previously reinforced stimulus.

### Reversal learning and 5-HT

Reversal learning is known to depend on an OFC–striatal system in monkeys and rats. Fiber-sparing lesions of the OFC impair reversal learning, whether between visual objects in rhesus monkeys, marmosets (Dias *et al.*, 1996) or rats (Chudasama and Robbins, 2003), or between spatial locations in the rat (Boulougouris *et al.*, 2007). Part of the deficit in each case appears to be a tendency to perseverate in the previously reinforced response. In the past few years, it has become apparent that the ascending 5-HT systems powerfully modulate reversal learning at the level of the OFC. Thus, in marmoset monkeys, depletion of 5-HT selectively from the PFC produces striking deficits in reversal learning, particularly in serial reversal, where the contingencies are continually reversed upon attainment of the learning criterion (Clarke *et al.*, 2004, 2005). Microanalysis of responding during the reversal stage shows that the deficit is at least partly because of a perseveration of responding to the previously rewarded stimulus immediately following contingency reversal, implicating the failure of a response inhibitory control process. A further experiment has shown that the deficit is clearly perseverative in the sense that the 5-HT-depleted monkeys do not disengage from a previously reinforced stimulus; if it is removed and replaced by a novel stimulus, discrimination learning is normal (Clarke *et al.*, 2007). However, it is apparent that the ‘perseverative’ deficit again is more specific than would be expected of a global disinhibitory problem. First, performance on another type of shifting task, the extra-dimensional shift, which is more dependent on the lateral PFC, is *not* impaired by PFC 5-HT depletion (Clarke *et al.*, 2005). Second, an obvious way of explaining the perseveration is in terms of retarded resistance to extinction. However, a recent experiment has ruled out this mechanism, as OFC 5-HT depletion failed to affect extinction of a single (non-discriminated) rewarded response – although OFC DA loss did produce massive resistance to extinction (Walker *et al.*, 2008). A subsequent experiment on how PFC 5-HT loss affects the acquisition of control over behavior by conditioned stimuli (i.e., conditioned reinforcers) has indicated that the 5-HT loss appears to produce a ‘bias’ towards some aspects of the stimulus which can retard acquisition of new responding – this again contrasts with the effects of OFC DA loss which is associated with no such bias.

In more general terms, the link of 5-HT to reversal learning has been strikingly confirmed by other studies in primates – for example, linking the short-armed alleles of the 5-HT transporter polymorphism to inferior reversal learning (Izquierdo *et al.*, 2007). In humans, ATD slows response times (Murphy *et al.*, 2002) and increases errors to criterion during reversal learning (Park *et al.*, 1994; Rogers *et al.*, 1999b; Murphy *et al.*, 2002). Talbot *et al.* (2006) failed to find any significant effects of tryptophan depletion on reversal learning, but this may simply highlight possible heterogeneity of response due to genetic variation in response to low tryptophan.

One challenge that arises in studying reversal learning in humans is that simple versions of the task (such as those used with rats and marmosets) are typically not sufficiently difficult to be sensitive to drug manipulations. To address this issue, a probabilistic version of the reversal learning task was developed. In the probabilistic reversal task, subjects receive misleading feedback on 20 percent of trials. The behavioral and neural effects of 5-HT manipulations on probabilistic reversal learning in humans appear to be somewhat distinct from the effects of global prefrontal 5-HT depletion on classic reversal learning in rats and marmosets. A neuroimaging study of reversal learning in humans did not observe any effects of ATD on perseverative responding or OFC activity (Evers *et al.*, 2005). Instead, the authors found that ATD enhanced activity in the dorsomedial PFC in response to negative feedback throughout the task. Another study using the same task showed that acute SSRI (citalopram) administration impaired performance by increasing the tendency to switch following misleading negative feedback, which fits with the hypothesis that low 5-HT heightens responding to negative feedback (Chamberlain *et al.*, 2006). Similar behavioral and neural responses have been observed in depressed patients, and this mechanism is thought to underlie the ‘catastrophic response to perceived failure’ seen in depression (Taylor Tavares *et al.*, 2008).

In summary, 5-HT in the OFC appears responsible for biasing responding to particular aspects of the stimulus without necessarily being involved in control of the vigor of responding during extinction, whereas OFC DA has the opposite role. This dissociation may, of course, not hold for subcortical structures to which the OFC projects, such as the medial striatum, which is, however, also implicated in reversal learning (Clarke *et al.*, 2008).

Thus far, we have been unable to examine which 5-HT receptors are implicated in these behavioral effects in marmosets. However, we have begun such experiments in the rat, by using a simple spatial reversal paradigm which is also sensitive to OFC lesions (Boulougouris *et al.*, 2007). Systemic administration of the 5-HT<sub>2A</sub> receptor antagonist M100907 impairs reversal on this task, whereas the

5-HT<sub>2C</sub> receptor antagonist SB-242084 again had the opposite effect, in this case of facilitation of reversal learning – and in both cases, the effects appear to be mediated, at least in part, by perseverative responding (Boulougouris *et al.*, 2008). These findings may be theoretically important, as they appear to provide problems for the hypothesis that 5-HT is implicated in behavioral inhibition. As Figure 2 shows, whereas the 5-HT<sub>2A</sub> receptor antagonist ameliorates impulsive behavior, it induces perseverative responding during reversal. By contrast, the 5-HT<sub>2C</sub> receptor antagonist exacerbates impulsive responding, but facilitates reversal learning. It is difficult to see how a unitary response inhibition mechanism could account for this. Either there is a common effect on another mediating variable (e.g., anxiety or enhanced aversiveness) which accounts for both effects, or they are controlled by separate neuronal circuitries with differing involvement of 5-HT receptors. Given the involvement of an OFC-medial striatal circuitry in aspects of compulsive behavior, and the IL-PFC-nucleus accumbens in impulsive responding, this does appear plausible. A clear conclusion, however, is that impulsivity and compulsivity do appear to be distinct behavioral constructs, and probably have separate if interactive roles in the explanation of such syndromes as OCD and ADHD, and also substance abuse.

## Conclusions

We have reviewed studies in experimental animals and humans, mainly from the perspective of our own studies, on the role of 5-HT in inhibitory control and reinforcement processing, relevant to such constructs as impulsivity, compulsivity and anxiety. Progress has clearly been made with respect to theories of central 5-HT function, although, as initially admitted, it is very difficult to arrive at a unitary role for such a complex system. Nevertheless, a few generalizations can be made. The functions of 5-HT in global behavioral inhibition are increasingly questioned; however, 5-HT depletion may especially ‘disinhibit’ responding in situations in which ‘waiting’ is required, perhaps through an exaggeration of the negative aversive qualities of the waiting period. A comparison of effects of 5-HT manipulations on paradigms tapping ‘impulsivity’ and ‘compulsivity’ suggests again that a behavioral construct such as ‘inhibition’ cannot adequately account for the findings. The effects of 5-HT loss on perseveration in monkeys also argue against a simple inhibitory account, in favor of one suggesting a modulation of the OFC in the control of stimulus preference. This theme that manipulations of 5-HT can bias the emotional processing of salient stimuli is consistent with many of the effects of 5-HT manipulations in humans, where, for example, mild and

transient 5-HT loss leads to a bias to respond to negative feedback and to exhibit heightened aversive responses to emotional stimuli. We have also raised the possibility of specific effects of 5-HT manipulations on higher cognitive processes such as decision-making cognition, suggesting specific functions for this neurotransmitter in brain regions such as the prefrontal cortex. Here, the question is whether such effects ultimately derive from actions of 5-HT in lower level processes. The resolution of these paradoxes has been part and parcel of research on 5-HT functions in health and disease over the past 50 years or so. We assume that this will be possible as we understand the impact of current manipulations in more detail in the context of those neural systems on which they impinge, as new methods for studying the role of 5-HT emerge, and as knowledge about the precise functions of the different neural systems modulated by 5-HT accrues.

# Experimental Studies on the Role(s) of Serotonin in Learning and Memory Functions

Jean-Christophe Cassel\*

*Laboratoire d'Imagerie et de Neurosciences Cognitives, Université de Strasbourg FRE 3289 Uds-CNRS,  
IFR 37 des Neurosciences, Strasbourg, France*

**Abstract:** In invertebrates, serotonin (5-HT) is involved in both non-associative and associative learning, and thus memory formation. Indeed, as shown in *Aplysia californica*, snails, leeches, etc., whereas the formation of memories is more difficult after 5-HT depletion, it is facilitated when serotonin functions are stimulated. Although it is generally considered that the evolution can be relatively conservative, the overall picture is much more complicated in higher vertebrates: when 5-HT systems are selectively damaged, the lesions have behavioral consequences, as can be evidenced, for instance, in rats or mice (e.g., on impulsivity), but learning is still possible, and most often memory capabilities appear normal. Serotonergic functions may also be enhanced by pharmacological tools, such as drugs inhibiting the reuptake of 5-HT (SSRIs). Although there is no consensus in the literature, SSRIs may have two types of effects according to whether they are given before or after training. When SSRIs are given before training, memory functions appear unchanged in some reports or altered in others; exceptionally, they can be improved. Given immediately after training, such drugs have no effect on memory or may improve it. In higher vertebrates, modifications of 5-HT functions have nevertheless consequences on the mnemonic impact of treatments affecting other neurotransmitter functions, such as blockade of cholinergic receptors or cholinergic lesions. Therefore, with regard to learning and memory, one of the roles of the ascending serotonergic system taken as a whole could be to modulate more direct functional implications of other neurotransmitter systems. These modulations could operate in a region-specific and perhaps receptor-specific manner.

**Keywords:** 5-HT, invertebrates, learning, memory, serotonin, vertebrates.

**Abbreviations:** 5-HT, 5-hydroxytryptamine (or serotonin); 5,6-DHT, 5,6-dihydroxytryptamine; 5,7-DHT, 5,7-dihydroxytryptamine; CNS, central nervous system; cAMP, cyclic adenosine monophosphate; CREB, cAMP response element-binding; GABA, gamma-amino butyric acid; MAPK, mitogen-activated protein kinase; MDMA, 3,4-methylenedioxymethamphetamine (or 'ecstasy'); pCA, parachloroamphetamine; PCPA, parachlorophenylalanine; PKA, protein kinase A; SSRI(s), selective serotonin reuptake inhibitor(s); THA, tetrahydroaminoacridine; THC,  $\Delta^9$ -tetrahydrocannabinol.

## Introduction

Since (1) the discovery by Vittorio Erspamer and Maffo Vialli of the substance they named enteramine (Erspamer and Vialli, 1937); (2) the isolation and chemical characterization of this indole by Irvine Page, Arda Alden Green and Maurice Rapport (Rapport *et al.*, 1948a, 1948b; Rapport, 1949), who named it serotonin (5-HT); (3) its subsequent discovery as a neurotransmitter in the invertebrate smooth muscle by Betty Mack Twarog (Twarog and

Page, 1953); and, finally, (4) the suspicion that it might be a neurotransmitter involved in mental illness by Dilworth Wayne Wooley (Wooley and Shaw, 1954), research on 5-HT has been the focus of sustained and widespread investigations extending ramifications in all possible corridors of basic and applied pharmacology (neuro)psychopharmacology, psychiatry and neuroscience. The fact that virtually all regions of the mammalian brain receive serotonergic afferents arising from two relatively small nuclei of the midbrain, namely the dorsal and medial raphe – also called B6–B7 and B8–B9 groups in Dahlström and Fuxe's (1964) nomenclature – is probably not the least reason why 5-HT has generated such a fascination in the scientific community. Not only is it one of the most ancient signaling

\*E-mail: jean-christophe.cassel@linc.u-strasbg.fr

molecules (Azmitia, 2007; Nichols and Nichols, 2008); also, to exert its pharmacological actions, this neurotransmitter has 14 different receptor targets classified into 7 families denominated 5-HT<sub>1</sub>–5-HT<sub>7</sub> (see, for example, Hoyer *et al.*, 2002; Nichols and Nichols, 2008). Most of these receptors have been described to participate, in one way or another, in a large variety of physiological and behavioral functions, including pain, feeding, sleep, sexual behavior, cardiac regulation, and both cognitive and emotional processes. Actually, it has become more and more apparent that where there is behavior, even at a very primary level in the evolutionary tree, there is a place for 5-HT.

The current chapter reviews some of the data from the literature indicating that mechanisms driven or modulated by 5-HT may participate in learning and memory functions. In no case, however, has the present chapter the pretension to provide an exhaustive overview of the vast literature on the implications of 5-HT in learning and memory functions. A Pubmed search performed on 3 September 2008 using ‘[(serotonin OR 5-HT) and (memory)]’ and ‘[(serotonin OR 5-HT) and (learning)]’ as combinations of keywords yielded 1660 and 4197 articles or reviews, respectively. Clearly, a list of 4197 references would probably cover at least 100 pages in a typical handbook, and reading all of them in order to compile their contribution into a short book chapter not exceeding 20 pages is probably anything but a realistic enterprise. Thus, rather than trying to achieve inaccessible completeness, the chapter will focus on a series of experiments in which serotonergic systems have been manipulated, mainly in terms of lesions or drug actions, in order to understand if and to what extent they contributed to learning and memory functions. Although mice and rats are very commonly used in such experiments, the chapter begins by considering a series of experiments carried out in animals having a much simpler nervous system – namely, invertebrates. Invertebrates, as will be illustrated, also encode, consolidate and retrieve information from their environment. Therefore, the role of 5-HT in memory functions is certainly easier to investigate and describe in such (sometimes very) simple organisms than in the higher vertebrates. Ideally, this chapter should have also covered the implications, as far as they are known, of the various 5-HT receptor types and subtypes in learning and memory functions. This task, though, would probably deserve one chapter per receptor family for which data are available in the literature.

### Exploring the role of serotonin in memory using invertebrate system models

#### *Serotonin and adaptation of the gill withdrawal reflex in Aplysia californica*

In 1894, Santiago Ramon Y Cajal (see also Jones, 1994) proposed that the material substrate of memory formation

could be the establishment of new connections between neurons. In 1949, Hebb proposed that learning and memory might rely upon experience-triggered functional reorganizations that can become lasting within neuronal networks (Hebb, 1949). About 20 years after this proposal, one of the three 2000 Nobel Prize Laureates in Physiology or Medicine, namely Eric Kandel, was seeking a simple animal model on which cellular and molecular studies of memory substrates would become possible. He started to work on an invertebrate named *Aplysia californica*, a giant marine snail (30 cm in length and 1 kg in weight for an adult specimen) which offers three major advantages: the number of neurons in its nervous system is relatively limited (about 20,000, to be compared with the 10<sup>12</sup> neurons of the human brain); these neurons are large, even gigantic (sometimes 1000 μm in diameter); and many of them are uniquely identifiable (among other reasons, because of their particular pigmentation). It is perhaps worth remembering that neuronal gigantism had already been a wonderful and extremely precious partner in the discovery of the mechanisms underlying the generation of an action potential and its propagation along the axon (see, for example, Huxley, 2002). In addition, an *Aplysia* displays various forms of non-associative (habituation, sensitization, dishabituation, desensitization) or associative (classical or operant conditioning) learning capabilities. Kandel focused his interests on the so-called gill withdrawal reflex, which is a protection reflex: when the siphon is subjected to the application of a tactile stimulus, the snail retracts it and withdraws its gill under the mantle shelf (Figure 1). The functional characteristics of this reflex can be altered by three types of learning: habituation (the reflex undergoes weakening as a consequence of repeated stimulations), sensitization (the reflex becomes stronger as a result of an aversive shock), and classical conditioning (a neutral stimulus, which normally produces a weak or no reflex, is able to elicit this reflex as a result of its repeated association with an unconditioned stimulus invariably producing a marked reflex).

These forms of learning were found in higher vertebrates, including humans, and undergo a conversion from a short-term storage which is sensitive to interference to a long-term storage that depends on protein synthesis and is resistant to interference, as largely described in mammals. Schematically, in the *Aplysia*, a short-term memory is generated when stimulations eliciting the withdrawal reflex are weak or sparse. Conversely, a long-term memory establishes when the stimulations are more intense, numerous, repeated and/or grouped. In 1976, Castellucci and Kandel reported that following sensitization of the gill-withdrawal reflex, at precisely the synapse linking sensory and motor neurons, the amount of 5-HT released in response to the application of a tactile stimulation to the siphon was increased, and that this modification could

**Figure 1** A dorsal view of an *Aplysia* showing the animal's respiratory organ: the gill. When the siphon is stimulated by the application of a tactile stimulus, the siphon is contracted and the gill is withdrawn under the mantle shelf (right, top). This withdrawal reflex is a protection reflex that undergoes habituation (right, middle) when the stimulation is repeated, or which may show sensitization after a noxious stimulus is applied to another part of the body (e.g., a hurt on the tail; right bottom). Dishabituation (not illustrated) is a term used to describe what happens once habituation has been established and a noxious stimulus is applied to another part of the body; in this case, the habituation of the withdrawal reflex is relieved. The scattered line indicates the limits of the non-retracted gill, as shown on the *Aplysia*, (left). To see the full color version of this figure please refer to the color plate in the back of the book. Copies produced via our print on demand service do not contain color plates. If your copy does not have the color plate, please go to this website to view the figure in color [www.elsevierdirect.com/companions/9780123746344](http://www.elsevierdirect.com/companions/9780123746344)

last for days, and even weeks. Moreover, the sensitization response could be induced by application of 5-HT and blocked by treatment with the 5-HT<sub>2</sub> receptor antagonist cinanserin, or the mixed 5-HT<sub>1</sub>/5-HT<sub>2</sub> antagonist cyproheptadine (Brunelli *et al.*, 1976; Mercer *et al.*, 1991). It is also noteworthy that lesions of the serotonergic neurons, which were produced with 5,7-dihydroxytryptamine (5,7-DHT; see below), reduced the synaptic facilitation response, as well as the dishabituation of the gill-withdrawal reflex (Glanzman *et al.*, 1989; see Figure 1). Although Glanzman *et al.* (1989) did not study the sensitization response in their lesion experiment, it is noteworthy that dishabituation can be induced in habituated animals using the same kind of manipulations as those leading to sensitization in non-habituated animals.

What, exactly, is the role of 5-HT in this type of learning? In fact, as concerns short-term memory, by acting on a variety of 5-HT receptor subtypes, of which four have been cloned (Barbas *et al.*, 2003), 5-HT is able to activate a second messenger system involving cAMP. 5-HT applications result in increased cAMP levels (Cedar and Schwartz, 1972), and direct injections of cAMP into presynaptic neurons is sufficient to induce presynaptic facilitation (Brunelli *et al.*, 1976). It was also shown that this facilitation involved PKA and the phosphorylation

of K<sup>+</sup> channels (Klein and Kandel, 1980). Conversely to these 5-HT-triggered processes underlying short-term memory, the long-term memory processes, which make the memory available for days, weeks or longer, require protein synthesis – a major step of trace consolidation. In case of repeated stimulations, the 5-HT-triggered cAMP rise persists for minutes, which enables activation of PKA and, consequently, of MAPK, which are both translocated to the nucleus, where they activate a transcriptional cascade involving CREB-1. The injection of a phosphorylated form of *Aplysia* CREB-1a is able to initiate long-term memory (in fact, lasting synaptic facilitation) in the absence of any other manipulation (Bartsch *et al.*, 1998). Downstream to this process, the growth of new synaptic connections is initiated, and these connections may last as long as the memory is present (Bailey *et al.*, 1992a, 1992b). Thus, in the *Aplysia*, under the influence of an appropriate experience, a 5-HT-triggered mechanism is changing the signal transmission characteristics between sensory and motor neurons. This modification may be triggered by different molecular and cellular mechanisms which underlie short- and long-term memory of sensitization of the gill-withdrawal reflex. In both cases, there is one crucial conductor in this biochemical orchestra: 5-HT!

### Serotonin and learning in other invertebrates

Interestingly, lesions of serotonergic neurons or other manipulations of serotonergic functions in other invertebrates (e.g., drosophilae, leeches, slugs, snails, worms) may also alter learning and memory capabilities (see, for example, Balaban *et al.*, 1987; Zakharov and Balaban, 1987; Ehrlich *et al.*, 1992; Sahley, 1994; Shirahata *et al.*, 2006). For instance, in a snail (*Helix lucorum*), Zakharov and Balaban (1987) found that the ability to develop avoidance-conditioned responses was dependent on the levels of 5-HT. When these levels are low, such as during the first post-hatching month, conditioning sessions do not result in memory formation. Conversely, when 5-HT levels are higher, as is the case later on in adults, the conditioning leads to memory formation. Interestingly, when 5-HT levels are depleted by 5,7-DHT treatment in adult snails, the latter again behave as do the immature ones: there is no memory formation. In a terrestrial slug (*Limax valentianus*), Shirahata *et al.* (2006) found that the memory for odor-taste associative learning could be disrupted by an about 55 percent reduction of 5-HT levels: after depletion, the slugs were unable to exhibit evidence for short-term memory (tested with a 24-hour post-acquisition delay), while their long-term memory (post-acquisition delay of 5 or 6 days) was normal. That short-term memory may be affected by 5-HT depletion whereas long-term memory is not might sound a bit surprising, if not enigmatic, especially when considering that before being consolidated for days or weeks, a memory must have existed in a kind of short-term buffer. The authors of this work nevertheless regard their findings as an indication that the mechanisms involved in each type of memory are different, one being 5-HT-dependent, the other not. These data also suggest that short- and long-term memories in slugs are processed separately from the beginning of the acquisition onwards. This interpretation appears compatible with findings showing that in *Aplysia*, although being both depending on 5-HT, short- and long-term memories have different processing pathways, the former being blocked by cyproheptadine, a 5-HT receptor antagonist, but not the latter (Emptage and Carew, 1993). However, this interpretation seems to ignore that short- and long-term memories are induced by different conditioning protocols (see above).

In a recent report, Sitaraman *et al.* (2008) demonstrated that 5-HT was critical for place memory formation in a fly, namely *Drosophila*. Briefly, flies were trained in a two-compartment heat box. When, during training, a fly crossed the midline in one direction, the box rapidly (within seconds) heated up to reach 41°C – a temperature the fly will spontaneously avoid when possible. When the fly again crossed the midline and returned to the

first compartment, the box cooled down to 24°C. After efficient training, a normal fly learned to avoid the compartment associated with the onset of heating. Sitaraman *et al.* (2008) genetically manipulated the serotonergic and dopaminergic neurons, and found that flies in which 5-HT levels were decreased by about 80 percent and dopamine levels by about 75 percent exhibited weak memory performances. This memory deficit could be reproduced by blocking synaptic transmission from serotonergic neurons or, in wild-type flies, by pharmacological reductions of 5-HT levels. It was shown to be independent of the dopaminergic system. The authors of this work also elegantly demonstrated that the various genetic manipulations in their flies did not affect thermosensitivity, indicating that their nervous system was still able to ‘process’ the heated compartment as potentially hazardous.

A series of experiments has also been carried out in the leech (*Hirudo medicinalis*). For instance, after the report by Moss *et al.* (2005) showing that 5-HT modulated the axonal coupling between the neurons (the so-called S cells), which plays a critical role in the sensitization of the shortening reflex (a tactile stimulation induces whole-body shortening), Burrell and Sahley (2005) demonstrated that the 5-HT-induced potentiation of S-cell excitability could be blocked by a 5-HT receptor antagonist (methysergide), a G-protein inhibitor (GDP- $\beta$ -S) and a PKA inhibitor (Rp-cAMP). They also found that the effects of 5-HT could be mimicked by a cAMP analog that activates PKA (db-cAMP). Methysergide and GDP- $\beta$ -S prevented learning-induced potentiation of S-cell excitability, as well as the excitability change that accompanies sensitization. When the preparations were exposed to the 5-HT antagonist or the G-protein inhibitor, the sensitization of the shortening reflex could not be acquired. In this organism, Catarsi *et al.* (1990) had already detected that the efficiency of a simple form of non-associative learning followed the seasonal variation in 5-HT levels, being maximal when the 5-HT levels were highest.

5-HT seems to play a role in memory formation in even a much simpler invertebrate organism, namely a nematode. The nematode *Caenorhabditis elegans* has a very simple nervous system, which is made of only 302 neurons (more than 60 times less than in *Aplysia californica*). In a recent report, Zhang *et al.* (2005) have shown that such worms displayed a relatively complex learning faculty, as they were able to associate chemosensory stimuli with illness and subsequently to avoid the illness-associated stimuli when they were given an opportunity to make a choice. In their study, Zhang and colleagues bred their worms, which feed on bacteria, in the presence of pathogenic or non-pathogenic bacteria. Those bred on the pathogenic regimen were found later to significantly avoid it when given the choice between this regimen

and a non-pathogenic one. Interestingly, 5-HT seems to play an important role in this learning. Indeed, worms raised on the pathogenic regimen showed increased 5-HT levels in several neurons, including chemosensory ones. Furthermore, worms that underwent a mutation of the gene coding for tryptophan hydroxylase, which resulted in 5-HT depletion, were unable to establish the association between the pathogenic bacteria regimen and illness. Although these data demonstrate a faculty to learn a relatively complex association, the findings reported by Zhang *et al.* (2005) do not unequivocally demonstrate that 5-HT is part of the mechanism of the memory formation process. They do, however, show that 5-HT is an important triggering signal in relation to the memory regarding the pathogenic bacteria.

### **Concluding remarks**

In invertebrates, 5-HT appears to play a crucial role in the establishment of non-associative and associative learning experiences. In the case of functional disruption of the 5-HT system, memories are more difficult or impossible to establish. On the contrary, in some of these animals, an increase of 5-HT functions may facilitate learning. Given the principle of conservatism of adapted mechanisms along the phylum, it is reasonable, as stated by Kandel (2001), to consider that cellular and molecular processes used by the *Aplysia* and other invertebrates to store either short- or long-term memories may also be used in vertebrates, including mammals. Therefore, it makes sense also to tackle the role of 5-HT in memory processes in vertebrates, and perhaps, before anything else, in the most common laboratory animals – namely, mice and rats.

### **Exploring the role of serotonin in memory by alterations of the 5-HT system in higher vertebrates**

In higher vertebrates, it is not possible to study memory processes at the level of a single particular neuron or synapse that would have its exact and easily identifiable equivalent within a particular brain structure of any subject of a given species. In approaches in higher vertebrates, the reasoning is usually focused on particular neuroanatomically defined serotonergic systems – in general, the dorsal and/or medial raphe. The functional outputs of these nuclei can be pharmacologically enhanced by administration of 5-HT-releasing substances or dietary tryptophan loading (rarely used), or, contrarily, depleted by the means of selective lesions, blockade of 5-HT synthesis or tryptophan-depleted food regimens (used more frequently than tryptophan loading, especially in human studies). The role of 5-HT can also be studied by

direct intraparenchymal infusions of 5-HT, or of a variety of substances that more or less specifically activate or block the numerous 5-HT receptors (see Figure 2). As outlined hereafter, however, the approaches are much more complicated than in invertebrates, in terms of identifying the role(s) of 5-HT in memory functions.

### **Enhancing 5-HT functions**

#### *Inhibiting 5-HT reuptake*

One of the most frequent methods used to boost the 5-HT systems is based on the administration of selective serotonin reuptake inhibitors (SSRIs) such as fluoxetine or citalopram. It must be kept in mind, however, that the administration regimen is a very important issue that must be considered in the interpretation of the drug effects on learning and memory performance. Indeed, when given acutely, SSRIs lead to the stimulation of 5-HT receptors at the postsynaptic level by increasing the availability of 5-HT in the synaptic cleft, but at the same time reduce (sometimes dramatically) the activity of the 5-HT system by a sustained action of 5-HT at the somato-dendritic inhibitory 5-HT<sub>1A</sub> receptors, which respond in the nanomolar range. When SSRIs are given subchronically or chronically, however, these 5-HT<sub>1A</sub> receptors undergo substantial down-regulation, whereby the net effects of such drugs become predominantly postsynaptic and correspond to a genuine activation of the 5-HT system.

An indication that SSRIs might interfere with memory formation can be derived from the report by Stewart and Reid (2000). Focusing on the hippocampal formation, these authors observed that repeated electroconvulsive stimulations, a treatment known to disrupt consolidation processes (see, for example, Sara and Hars, 2006), produced long-term potentiation in the perforant paths to granule-cell synapses that could be mimicked by fluoxetine treatment. While electroconvulsive stimulation disrupted spatial learning capabilities, however, fluoxetine left the latter intact. Keith *et al.* (2007) also reported that spatial learning was not affected by fluoxetine treatment of intact rats. However, when rats were subjected to lesions of the granule cells of the dentate gyrus, a hippocampal sub-region, such a treatment prevented recovery of function. Using other models of amnesia, which consisted of treating rats with a muscarinic receptor antagonist (scopolamine) or a cannabinoid receptor agonist ( $\Delta^9$ -tetrahydrocannabinol, or THC), Egashira *et al.* (2006) found that a low dose of citalopram was able to attenuate the amnesic effects of scopolamine or THC in a spatial memory task (the radial maze). Using a water-maze task, Yau *et al.* (2002) found chronic fluoxetine treatment to have no effect on performance, whether in a population of

**Figure 2** Alterations of the serotonergic system/synapses can be achieved by different methods. Depletion may be obtained by irreversible damage to the neurons by the means of intracerebroventricular 5,7-dihydroxytryptamine (5,7-DHT), which is taken up by the serotonin transporter (a), by pCPA-induced blockade of the 5-HT-synthesizing enzyme, tryptophan hydroxylase (b), by placing subjects under tryptophan-depleted food regimens (c), or by pCA- or MDMA-induced alterations of 5-HT terminals (d). Increased 5-HT functions can be obtained by acute pCA-induced release of 5-HT (e), by blockade of the serotonin transporter (SERT; f), or the administration of tryptophan-enriched food regimens (g). Another way to interfere with serotonergic function is based on the administration of ligands that may more or less selectively block (antagonists) or activate (agonists) the receptors (h), which are of the metabotropic (5-HT<sub>1</sub>, 5-HT<sub>2</sub>, 5-HT<sub>4</sub>, 5-HT<sub>7</sub>) or inotropic (5-HT<sub>3</sub>) type; depending on the species, the autoreceptor is of the 5-HT<sub>1B</sub> or 5-HT<sub>1D</sub> subtype. As regards the receptors, it is also possible to genetically delete them in mice (i). In general, (d), (g) and (h) can be used both in experimental animals and human subjects, but all other approaches are restricted to animal models (most often to mice, rats, monkeys, less frequently to guinea pigs, as concerns the study of CNS functions). To see the full color version of this figure please refer to the color plate in the back of the book. Copies produced via our print on demand service do not contain color plates. If your copy does not have the color plate, please go to this website to view the figure in color [www.elsevierdirect.com/companions/9780123746344](http://www.elsevierdirect.com/companions/9780123746344)

young adult rats or in a population of old rats exhibiting an age-related impairment. Valluzzi and Chan (2007) confirmed that fluoxetine (chronic treatment) had no effect on water-maze learning, but impaired hippocampal-independent learning in an object recognition task and an appetitive Pavlovian-conditioning task. Using citalopram or fluoxetine, Burghardt *et al.* (2007) recently reported that both drugs, when injected before the test following a drug-free acquisition, were able to exacerbate the expression of previously acquired conditioned auditory fear. This finding, however, does not demonstrate a facilitation of trace retrieval. Rather, it shows that SSRIs may produce symptoms of anxiety that contribute to the potentiation of the expression of fear. This observation is at variance with the report by Hashimoto *et al.* (1996), who found that the pre-testing administration of citalopram reduced freezing to a fear-conditioned context. Interestingly, when citalopram was given before the conditioning, acquisition of the auditory fear was ameliorated (Burghardt *et al.*, 2004). However, there has been a report on weaker freezing in a fear-conditioned context after pre-conditioning citalopram

treatment (Inoue *et al.*, 1996). Thus, it seems that, depending on whether conditioning is auditory or contextual, pre-conditioning or pre-testing administration of SSRIs has opposing effects. This can be linked to the fact that auditory conditioning relies upon amygdala-dependent processes, whereas contextual fear conditioning engages both the amygdala and the hippocampus. Interestingly enough, Burghardt *et al.* (2004) have reported a marked difference in the effects of citalopram on fear acquisition: while acute treatment facilitated auditory fear acquisition (probably because of a pharmacologically induced anxiety), chronic treatment in fact attenuated it. For more data on the effects of SSRIs on memory the reader is referred to the excellent review by Monleón and colleagues (2008), in which the authors point to a memory-impairing effect of SSRIs given before training, against an absence of impairing effects when such drugs were administered after training. In general, these authors conclude that the effects of SSRIs could be memory phase-dependent, being detrimental during encoding and early consolidation, and beneficial during later consolidation phases and retrieval.

### *Stimulating 5-HT release*

Parachloroamphetamine (pCA) has also been used to boost 5-HT function. This may seem paradoxical, as this drug is often used to produce 5-HT depletion. In fact, this molecule has opposing effects depending on the post-administration delay. Shortly after administration it induces a massive release of 5-HT from the terminals, but then, in the long-term, destroys at least part of these terminals (Fuller, 1992). When used as a 5-HT-releasing agent, pCA treatment was found to impair acquisition of a passive avoidance response. Indeed, when injected before training, pCA produced a dose-dependent alteration of retention performances assessed with a 24-hour delay (Misane and Ögren, 2000); this alteration was not attributable to serotonergic toxicity. Similar findings were subsequently reported by Solana-Figueroa *et al.* (2002), who concomitantly demonstrated that this impairment could be attenuated by an increase of the foot-shock intensity, and thus more intense learning. In general, these observations are in agreement with the data reported earlier by Santucci *et al.* (1996), who also assessed the effects of acute pCA treatment on passive avoidance performance, and completed their approach on retention performance after eight-arm radial-maze training. In the passive avoidance task, Santucci *et al.* found a dose-dependent impairment of retention performance when pCA was injected 30 minutes before the training session. In rats that had achieved a good level of working- and reference-memory performance in a radial-maze task, treatment with pCA disrupted retrieval performance on the first day of administration, but not on two subsequent treatment days. All these observations are compatible with the idea that an increase of the serotonergic tonus can be detrimental to memory functions, either by altering consolidation processes or by interfering with recall.

### *Infusing 5-HT into brain regions*

Intuitively, this is probably the most direct approach that comes to mind to study the role of a neurotransmitter in a particular function. In addition, intraparenchymal (directly into brain tissue) infusions enable an acceptable neuroanatomical specificity, as the neurotransmitter can be infused in virtually any structure or region of the brain, whether superficial or deep in the organ. A major drawback of this approach is the fact that all mechanisms ensuring the inactivation of the latter (i.e., enzymatic degradation or reuptake) are still operating and may therefore reduce the half-life of the infused substance dramatically. Another drawback is that acute flooding of all neurotransmitter-specific receptors within a given brain region or system is probably all but physiological, because *in situ*, the various regulations operating in this region or system

certainly undergo a much finer multi-transmitter and receptor-specific neuropharmacological tuning than those mimicked by the receptor flooding. Nevertheless, there are a few studies in which 5-HT has been infused directly into regions such as the striatum, substantia nigra (which may participate in aspects of procedural memory), or amygdala and hippocampus (which may participate in aspects of 'declarative-like' memory). As regards the striatum, Prado-Alcalá *et al.* (2003) reported that an infusion of 5-HT into the posterior region of this structure after the acquisition of a step-through inhibitory avoidance task induced amnesia and thus disrupted consolidation processes. These observations are in line with the aforementioned acute effects of pCA administered into the striatum, a treatment resulting in the marked increase of 5-HT release from endogenous stores (see 'Stimulating 5-HT release', above). Díaz del Guante *et al.* (2004) also used an inhibitory avoidance task, but they infused 5-HT into the substantia nigra before the training session (*vs* cerebral cortex and zona incerta). Interestingly, the authors report a dose-dependent retention impairment, indicating that increased 5-HT activity in the substantia nigra may also produce anterograde amnesia. In earlier studies, 5-HT was infused into the amygdala (Plaznik *et al.*, 1985) or the hippocampus (Plaznik *et al.*, 1983) of rats before training, and was also found to impair the retention of a passive avoidance response.

### *Depleting 5-HT functions*

For many years, experiments in behavioral neurobiology relied upon lesion techniques that selectively damaged well-delineated regions of the brain (nuclei or/and pathways to various target structures) in order to assess the behavioral outcomes of such damage. While very useful in studying and establishing possible structure–function relationships, such approaches were of limited interest regarding our understanding of the neuropharmacological regulations involved in the modulation of region- or system-specific functions. That kind of investigation requires pharmacological approaches or/and lesion techniques that can be selective for particular neurotransmitter systems. With regard to the serotonergic systems, an approach based on neurochemical selectivity of the lesions became possible with the emergence of a series of compounds such as 5,6-dihydroxytryptamine (5,6-DHT) and 5,7-dihydroxytryptamine (5,7-DHT), which were able to produce damage to serotonergic neurons that was selective when noradrenergic neurons were protected by a pharmacological inhibition of the noradrenaline reuptake carrier (Baumgarten *et al.*, 1971, 1973a; Baumgarten and Lachenmayer, 1972). Subsequently, 5,7-DHT, which

proved to be more useful than 5,6-dihydroxytryptamine (the latter having a high non-specific toxicity and poor diffusion properties; Baumgarten *et al.*, 1973b), has been extensively used to damage serotonergic neurons in the rodent brain and to investigate the functional correlates of such damage at various levels of analysis, including memory. 5,7-DHT can be infused directly in specific brain regions such as the dorsal or/and median raphe. Its intraventricular administration to rats or mice, using a sufficient amount (generally about 150 µg), produces about 90 percent depletion of 5-HT in target structures such as the cortex and the hippocampus, with minimal or no damage to other monoaminergic systems. Moreover, this depletion is permanent. For the mechanisms of action of 5,7-DHT, the reader may refer to Sinhababu and Borchardt (1988) or Kawase *et al.* (1990). Alternatives to this lesion approach consist of treating the animals with parachlorophenylalanine (pCPA), which produces dramatic 5-HT depletion by inhibition of tryptophan hydroxylase, or with parachloroamphetamine (pCA; see above). Administration of 3,4-methylenedioxymethamphetamine (MDMA or 'ecstasy') at a high dose and under appropriate ambient temperature conditions may also produce serotonergic toxicity (see, for example, Green *et al.*, 2003). The potential problem with the latter compounds is that depletion, which may be massive with pCPA and pCA, is generally followed by protracted recovery, which can extend for over 1 year with MDMA (see, for example, Battaglia *et al.*, 1991). After pCPA treatment there is also a recovery, which is not detectable 3 days after administration but becomes significant after 8 days (Ben Hamida and Cassel, unpublished results). Furthermore, while MDMA affects serotonergic neurons in rats, it produces damage to dopaminergic neurons in mice (see, for example, Green *et al.*, 2003). In any case, lesions or depletion induced by one or the other of these compounds provide interesting data as to the role of 5-HT systems in learning and memory functions.

#### *5,7-dihydroxytryptamine (5,7-DHT) lesions*

There seems to be a relatively general consensus on the fact that 5,7-DHT-induced lesions do not alter learning and memory capabilities in a dramatic way. Early studies showed that electrolytic or ibotenate lesions of the median raphe impaired the acquisition of a delayed alternation task (Asin and Fibiger, 1984), and the same was true for the effect of an electrolytic lesion on performance in a radial-maze task (Asin *et al.*, 1985). In each of these reports, however, the authors also showed that when 5,7-DHT was injected into the median raphe, which induced 5-HT depletion as severe as following the electrolytic lesion, performance was comparable to that found in the controls, whatever the task (Asin and Fibiger, 1984;

Asin *et al.*, 1985). As electrolytic or ibotenate lesions were not selective, these observations suggest that it was not the disruption of serotonergic neurons that accounted for the behavioral effects of both other less-selective lesions. Similar conclusions were drawn from studies in which 5,7-DHT, whether injected intracerebroventricularly or intraparenchymally, did not alter the capability to acquire a reference memory in a water-maze task and subsequently to retrieve it in a probe trial, or to perform a working memory task in the same test apparatus (Nilsson *et al.*, 1988; Richter-Levin and Segal, 1991; Murtha and Pappas, 1994; Lehmann *et al.*, 2000, 2002; Galani *et al.*, 2007). While most data in the literature seem to support such conclusions, some issues need to be addressed.

First, lesions of serotonergic neurons in neonatal rodents may result in an alteration of some cognitive functions or behaviors relevant to cognition (e.g., anxiety) when the animals are young adults (e.g., Hohmann *et al.*, 2007; McLean *et al.*, 1993); spatial memory capabilities, however, appear to be preserved (Volpe *et al.*, 1992). In the approaches showing cognitive deficits, it is nevertheless possible that the lesions contribute to altering aspects of CNS development which, in the end, affect functional dynamics within non-serotonergic neurotransmission systems more crucial to memory functions.

Second, whereas the effects of 5,7-DHT lesions on long-term memory seem weak, short-term (or working) memory appears more susceptible to such lesions, although not all of the few available studies agree on this point (e.g., Wirth *et al.*, 2000). Hritcu *et al.* (2007) recently published an article in which they showed that 5,7-DHT lesions disrupted short-term memory processes, as assessed in a Y-maze alternation task and an eight-arm radial-maze task, whereas long-term memory capabilities were preserved. Using a T-maze alternation task in rats, Ricarte *et al.* (1993) found that 5,7-DHT lesions impaired choice accuracy. As this impairment was found with a 5-second inter-trial delay, and was still observed with up to a 3-minute one, it is compatible with an impairment of short-term memory processes. In another approach, Lieben *et al.* (2006) used an object recognition task in rats and found that serotonergic lesions altered the capability to identify a novel object as such (and thus to remember the familiar one) at a 1-hour delay between the exploration and testing sessions; unfortunately, longer delays were not tested. Along this line, it can be recalled that serotonergic lesions were also found to disrupt short-term memory in a terrestrial slug, while long-term memory was preserved (Shirahata *et al.*, 2006; see above). Finally, Cassaday *et al.* (2003) used a non-match to sample object recognition task in a Y-maze, and observed that rats with 5,7-DHT lesions were impaired in acquiring a working memory task but not in performing the task once

acquired. These rats were also impaired during the early phase of a T-maze alternation task. However, using a short-term memory olfactory recognition task, Wirth *et al.* (2000) did not observe deficits after 5,7-DHT lesions.

Third, it cannot be ignored that a few reports even demonstrated facilitating effects of 5,7-DHT-induced serotonergic lesions on memory functions. For instance, using the Stone 14-unit T-maze, Altman *et al.* (1990) found that infusion of 5,7-DHT into the fimbria–fornix/cingular bundle led to lesioned rats requiring fewer trials to reach a performance criterion than their intact counterparts. In a more recent study, Anguiano-Rodríguez *et al.* (2007) tested rats in a water maze for their ability to use only proprioceptive information in an egocentric learning task. The authors found that 5-HT depletion confined to the striatum facilitated this kind of learning, most probably by modulating dopamine functions. Similar observations were made when 5,7-DHT was injected into the cerebral ventricles (Olvera-Cortés *et al.*, 2001). Using the same kind of lesions, Ward *et al.* (1999) reported on facilitated acquisition of an operant conditional discrimination task; these authors also observed that the performance of the lesioned rats was less sensitive to parametric manipulations (changing the cognitive, sensory or motivational constraints of the task) as compared to sham-operated controls.

#### *Other approaches (MDMA, pCPA, pCA administration, dietary tryptophan restrictions)*

There are also a few studies assessing the effects on memory functions of other 5-HT-depleting treatments. Using a regimen of MDMA treatment that was toxic for 5-HT neurons, Morley *et al.* (2001) found that adult rats exhibited impaired object recognition performances when tested 15 minutes after training. Likewise, in rats that had been given MDMA every fifth day between the ages of 35 and 60 days, and were then tested at the age of 65 days, object recognition performance was impaired (Piper and Meyer, 2004). Rats treated with a neurotoxic regimen of MDMA have also been tested in both the Cincinnati water maze (made of nine interconnected and flooded T-mazes in which rats have to learn the only possible pathway between a start and a goal location) and the more classical Morris water maze (Able *et al.*, 2006). In both tasks, the rats given MDMA and exhibiting depleted 5-HT levels showed modest but significant impairments. As was the case with 5,7-DHT, in the study by Skelton *et al.* (2006), the effects of MDMA have also been addressed in rats intoxicated as juveniles (between 1 and 10 or 11 and 20 postnatal days) and subsequently tested when young adults (at about 60 days). Whatever the age of intoxication, MDMA produced comparable 5-HT depletion (assessed at the age of 105 days). In both

a sequential and a spatial reference-memory task in the water maze, rats given MDMA showed a slight but significant impairment, although only when the treatment was given between 11 and 20 days, which again raises the question of the exclusively serotonergic nature of the reported deficits. As already mentioned regarding the effects of neonatal administration of 5,7-DHT, developmental abnormalities may have contributed as well. In the study by Ricaurte *et al.* (1993), the neurotoxic regimen of MDMA had no effect on percent alternation in a T-maze. Finally, in a study by Robinson *et al.* (1993), MDMA-induced 5-HT depletion had no effect on a series of behavioral tests taxing the place–navigation learning set, skilled forelimb use, and the ability to make complex judgements regarding the stimulus properties.

In adult rats, pCPA also was found to alter spontaneous alternation in a T-maze, although it had no effect on passive avoidance tested with a post-acquisition delay of 24 hours (Hritcu *et al.*, 2007). This observation is compatible with the idea that 5-HT depletion induces short-term memory impairments. In most studies, however, pCPA had weak or no effects on a variety of learning and memory tasks (Richter-Levin and Segal, 1989; Vanderwolf *et al.*, 1990; Riekkinen and Riekkinen, 1994; Beiko *et al.*, 1997; Bertrand *et al.*, 2001).

Similar approaches were carried out in rats subjected to pCA-induced depletion of 5-HT. Some studies reported no effect on working memory performance (Sakurai and Wenk, 1990; Jäkälä *et al.*, 1993a), or even on spatial working memory (Altman *et al.*, 1989). Others found the treatment to improve learning capabilities in the Stone 14-unit T-maze (Altman *et al.*, 1989; Normile *et al.*, 1990). In a study assessing passive avoidance retention, Heinsbroek *et al.* (1988) found that the effects of pCA were dependent on the sex, with untreated males performing better than females during the retention test, but this difference was abolished after pCA treatment. The authors of the latter study nevertheless excluded that the effects of pCA were due to memory disruption.

Finally, using a tryptophan-restricted food diet in rats, González-Burgos *et al.* (1998) found that rats with brain 5-HT reduction (which was not measured in this study) were faster than their normally fed controls in learning a pathway between a start and a goal box in the Biel maze (a maze in which rats have to learn the only possible way between a start and a goal box).

#### *Concluding remarks*

Whereas among various invertebrates, such as the Aplysia, the leech, worms, etc., the role of 5-HT in the generation of associative memories appears relatively comparable, the

outcome of studies aiming at boosting or depleting serotonergic functions in vertebrates, and especially in extremely common laboratory mammals such as mice and rats, is much more variable. Based on the latter studies, it is not possible to achieve a clear and consensual view regarding the role of 5-HT in learning and memory functions. For many learning and memory tasks, whether associative, spatial or other, it seems that general depletion of the serotonergic systems has no or rather positive consequences on memory function, whereas general boosting has usually no or rather negative consequences. It is noteworthy, however, that for each series of results that tend to support the latter assertion, whether in the positive or negative directions, there are several studies providing qualifying or even contradictory data. A relatively accurate way to characterize the involvement of the serotonergic systems in learning and memory functions in mammals would therefore consist of considering it as not absolutely crucial to such functions, while able to participate in their modulation by, for example, influencing the outputs from other systems which are perhaps more directly implicated in learning and memory processes. One such neurotransmitter system could be constituted by the cholinergic system of the basal forebrain, although the role of the septo-hippocampal cholinergic projections in memory has been subjected to discussion based on data obtained with highly selective and extensive cholinergic lesions in the septal nuclei (for review, see Parent and Baxter, 2004). The involvement of the cholinergic basalo-cortical pathways in memory is not crucial (Galani *et al.*, 2002), but its contribution to attention seems much better established (e.g., Harati *et al.*, 2008).

#### **Manipulating other neurotransmitter systems in combination with alterations of 5-HT functions: the cholinergic system as an example**

If 5-HT modulates the functional outputs of another system involved in memory, then damage to or functional alterations of serotonergic neurons and neurons of this system should demonstrate a synergistic interaction. In this case, the result of a double lesion or acute pharmacological alteration should be – in quality and/or magnitude – significantly more or significantly less than a simple addition of the effects of each single lesion. Over the past, several studies have provided some support to such a view, the earlier of which generally relied upon approaches lacking neuroanatomical and/or neurochemical selectivity. Indeed, while the neurotoxin 5,7-DHT has been used since the early 1970s (Baumgarten and Lachenmayer, 1972), a toxin showing an excellent and consensually acknowledged selectivity for the cholinergic system (of the basal forebrain), namely 192 IgG-saporin

(for review, see, for example, Parent and Baxter, 2004), has been available only since the beginning of the 1990s (see, for example, Wiley *et al.*, 1991).

#### ***Cholinergic lesions in combination with 5-HT depletion***

##### *Non-selective cholinergic lesions*

One of the first experiments designed to explore the effects on memory of combined cholinergic and serotonergic lesions as compared to those of either lesion alone was made by Nilsson *et al.* (1988). These authors performed radiofrequency lesions of the medial septum in combination with 5,7-DHT lesions (the toxin was administered intracerebroventricularly) of the ascending serotonergic systems in the rat. Subsequently, they tested their animals using a classical Morris water-maze task that taxed spatial reference memory. In rats with only 5, 7-DHT lesions, there was no deficit. Conversely, rats with only a septal lesion showed an impaired ability to find the platform. In the animals bearing both lesions, however, the deficit was significantly larger than with septal lesions alone. Subsequently, Richter-Levin and Segal (1991) published a study in which they had combined partial electrolytic lesions of the septal region with 5,7-DHT lesions of the serotonergic neurons. Neither single lesion affected Morris water-maze performance in a significant way, but after double lesions both reference- and working-memory performances were dramatically impaired. Murtha and Pappas (1994) reported similar conclusions in rats subjected to intraseptal injections of a neurotoxic dose of N-methyl-D-aspartate and intraforaminal infusions of 5, 7-DHT: only rats with double lesions were impaired in a water-maze task.

Serotonergic lesions were also combined with lesions of the nucleus basalis magnocellularis (NBM), another major cholinergic nucleus of the basal forebrain, which sends projections to the cortical mantle. For instance, Normile *et al.* (1990) used rats that sustained ibotenate-induced lesions of the NBM alone or in combination with systemic administration of pCA. Subsequently, these authors assessed the acquisition of a complex spatial discrimination task in a Stone 14-unit T-maze, in which the animals have to learn a route from a start to a goal box. The authors found that the rats given pCA alone showed better performance than their unlesioned counterparts. Although NBM lesions had no effect on spatial learning, they prevented the pCA-induced improvement. Riekkinen *et al.* (1990) compared the effects of separate or combined lesions of the dorsal raphe and the NBM on acquisition of a water-maze task in rats. These authors reported the dorsal raphe lesions to be ineffective, the NBM lesions to impair performance, and both lesions combined to induce

a deficit greater than that due to NBM lesions alone. Using passive-avoidance and water-maze tasks, Jäkälä *et al.* (1993b) investigated the consequences of NBM lesions produced by intraparenchymal quisqualic acid injections, or inhibition of brain 5-HT synthesis performed by systemic pCPA treatment, or both types of lesions combined. They found that NBM lesions severely impaired passive-avoidance retention and only slightly disturbed water-maze performance. pCPA alone had no effect in either of these tasks, but potentiated the effects of NBM lesions. Markowska and Wenk (1991) also compared the behavioral effects of NBM lesions (injection of ibotenic acid) combined or not with 5-HT depletion induced by systemic pCA treatment, but they used a non-spatial memory task (cued delayed non-matching to sample task) and investigated more precisely both the acute and long-term effects of the treatments. They found no effect of 5-HT depletion, whether shortly after treatment (4 weeks) or later on when testing was prolonged. In contrast, NBM lesions resulted in a deficit in the non-spatial memory task. Combined pCA treatment and NBM lesions did not produce a larger deficit than NBM lesions alone. However, when testing was prolonged, rats with NBM lesions showed some improvement over time, whereas those given both NBM lesions and pCA treatment did not. Overall, the effects of NBM lesions combined with 5-HT depletion on a delayed non-matching to sample task appeared to be rather weak – a conclusion that was in line with another report by Sahgal and Keith (1993), who also used a delayed non-matching to sample paradigm in rats given NBM lesions combined with 5,7-DHT-induced 5-HT depletion.

Thus, this series of experiments suggests that the cognitive effects of cholinergic denervation of the hippocampus (septal lesions) or of the neocortex (nucleus basalis lesions) can be exacerbated by concomitant 5-HT depletion. It is noteworthy, however, that the techniques used to perform the cholinergic damage were all but selective. In 1997, Matsukawa and colleagues published the data of an experiment in which they combined a pCPA treatment with an AF64A-induced lesion (AF64A is a cholinergic neurotoxin) and, beside other results, found the combined lesions to alter performance during the acquisition of a water-maze task. However, the cholinergic specificity of AF64A has been questioned (see, for example, Eva *et al.*, 1987); the variable that was considered to account for learning in the Matsukawa study (i.e., platform latency) is sensitive to non-cognitive biases, the deficit reported was weak, and learning was not prevented in the double-lesioned group (unfortunately, the authors did not report probe-trial performance). As regards the cholinergic selectivity of the lesions, 192 IgG-saporin would probably have been a better choice.

### *Selective cholinergic lesions*

To the best of our knowledge, we have been the first to use 192 IgG-saporin lesions in combination with another type of neurochemically selective damage, namely 5,7-DHT-induced 5-HT depletion (Lehmann *et al.*, 2000, 2002). In general, lesion experiments based on intracerebroventricular injections of 192 IgG-saporin and 5,7-DHT clearly suggest that the cognitive effects of a cholinergic denervation of both the hippocampus (septal lesions) and the neocortex (NBM) can be exacerbated by concomitant and widespread 5-HT depletion. Indeed, we found that 5,7-DHT, used in combination with 192 IgG-saporin, induced working-memory deficits in the water maze and in the radial maze, which neither toxin produced when injected alone. In that way, a study assessing behavioral (locomotor activity, forced T-maze alternation, beam-walking, Morris water maze and radial-maze) and neurochemical effects of intracerebroventricular injections of 192 IgG-saporin and of 5,7-DHT in adult Long-Evans female rats showed that cholinergic lesions, which reduced the concentration of acetylcholine by about 40 percent in the hippocampus but had no effect in the striatum, induced only severe motor deficits. Serotonergic lesions, which reduced the concentration of 5-HT by 80 percent in the hippocampus and the striatum, produced diurnal and nocturnal hyperactivity but no other behavioral effect. Finally, rats with combined lesions were more active than those with only serotonergic lesions, showed motor dysfunctions similar to those found in rats with cholinergic lesions alone, and exhibited impaired performance in the T-maze alternation test, the water-maze working-memory test and the radial-maze (Lehmann *et al.*, 2000). Another study conducted in our group showed that 5-HT depletion confined to the hippocampus – by injections of 5,7-DHT directly into the cingular bundle and the fimbria-fornix – could attenuate some of the behavioral deficits produced by a large dose of 192 IgG-saporin, which this time was injected directly into the medial septum and the diagonal band of Broca (Lehmann *et al.*, 2002). In this experiment, rats with single or combined damage were tested for locomotor activity, spontaneous T-maze alternation, sensorimotor, water-maze and radial-maze performance. The data showed that the cholinergic lesions, which decreased the hippocampal concentration of acetylcholine by about 65 percent (see also Chang and Gold, 2004), induced nocturnal hyperlocomotion, reduced T-maze alternation, impaired both reference-memory in the water maze and working-memory in the radial maze, but had no effect on sensorimotor performance and working-memory in the water maze. In the group of rats given combined lesions, all deficits produced by the cholinergic lesions were observed; surprisingly, however, the nocturnal hyperactivity and the working-memory deficits in the radial maze

were significantly attenuated. These results suggest that reduction of the serotonergic tone in the hippocampus may compensate for some dysfunctions subsequent to a loss of cholinergic hippocampal inputs. We have reason to believe that part of the mechanism could be some facilitation of acetylcholine release (Birchmeier *et al.*, 2003).

#### *Intrahippocampal grafts of cholinergic and serotonergic neurons*

Although this is probably less directly related to the topic of this chapter, it is also noteworthy that after extensive hippocampal denervation by fimbria–fornix lesions, and thus lesions altering cholinergic, GABAergic, noradrenergic and serotonergic afferents of the hippocampus, intrahippocampal grafts rich in cholinergic and serotonergic neurons and providing a neurotransmitter-specific neurochemical restoration to the hippocampus (see, for example, Cassel *et al.*, 1992a) were found to produce the most efficient benefit as regards recovery of memory functions (see, for example, Nilsson *et al.*, 1990; Jeltsch *et al.*, 1994; Balse *et al.*, 1999; but see also Cassel *et al.*, 1992b or 1997 for review). For instance, in rats given radiofrequency (and thus unselective) lesions of the medial septum combined with intracerebroventricular injections of 5,7-DHT, Nilsson and his collaborators measured the behavioral effects of septal grafts alone (which are rich in cholinergic neurons but devoid of serotonergic ones), of raphe grafts alone (which are rich in serotonergic neurons but largely devoid of cholinergic ones), and of a combination of both types of grafts (Nilsson *et al.*, 1990). All these grafts were placed into the hippocampus as a cell suspension preparation, and cognitive function was assessed several months post-grafting in a Morris water maze according to a protocol taxing reference memory. Whereas neither type of single grafts produced beneficial effects on maze performance, the combined grafts were able to improve this performance at a post-grafting delay of 10 months. Similar observations were made after electrolytic lesions (Jeltsch *et al.*, 1994) or aspiration lesions (Balse *et al.*, 1999) of the fimbria and the dorsal fornix. Under some circumstances (i.e., serotonergic lesions combined with partial cholinergic lesions in the septal region), it seems that even the sole serotonergic reinnervation of the hippocampus may be sufficient to promote significant recovery of spatial reference as well as working-memory performance (Richter-Levin *et al.*, 1993). All these data demonstrate an implication of serotonergic and cholinergic processes in cognitive function, and may perhaps fit with the idea of serotonergic modulation of some cognitive abilities in which cholinergic mechanisms have been recognized to contribute a significant role. This view is further supported by experiments that combined

pharmacological manipulations of the cholinergic system in 5-HT depleted animals.

#### *Cholinergic drugs in combination with 5-HT depletion*

Matsuno *et al.* (1993) found that pCPA-induced impairment in passive-avoidance learning in mice could be attenuated by the administration of tetrahydroaminoacridine (efficient dose: 10 mg/kg, p.o.) or physostigmine (efficient doses: 0.25 and 0.5 mg/kg, i.p.), two acetylcholinesterase inhibitors. Thus, a deficit induced by serotonergic depletion can be partially reversed by increasing the half-life of acetylcholine. Acetylcholine binds to muscarinic and nicotinic receptors.

In one of the first studies assessing the effects of muscarinic blockade in 5-HT-depleted rats, Vanderwolf (1987) compared the passive-avoidance and water-maze learning performances of intact rats to that of pCPA-treated rats exposed to scopolamine (5 mg/kg, s.c.) or atropine (50 mg/kg, i.p.) – two antagonists of muscarinic receptors – during acquisition or retention trials. Scopolamine disrupted acquisition more than retention, an effect mimicked by atropine. pCPA was ineffective (i.e., did not alter learning/memory functions), but scopolamine produced a larger deficit in pCPA-treated rats than in intact rats. These data show that the cognitive effects of muscarinic blockade may be potentiated by serotonergic depletion. Similar findings were reported by Richter-Levin and Segal (1989), who administered atropine (20 mg/kg, i.p.) to pCPA-treated rats tested in the water-maze task. These authors found that this dose of atropine disrupted spatial learning performance only in pCPA-treated rats; pCPA had no proper effect. Riekkinen *et al.* (1991a) tested intact and 5,7-DHT-treated rats for water-maze performance after scopolamine (0.8 mg/kg, i.p.) or pilocarpine (muscarinic agonist; 4 and 10 mg/kg, i.p.) treatment. While 5,7-DHT lesions produced no deficit, scopolamine severely impaired spatial learning in both intact and lesioned rats. In intact rats, the scopolamine-induced deficit was abolished by pilocarpine treatment at a dose of 4 mg/kg (i.p.), whereas in the rats with 5,7-DHT lesions a dose of 10 mg/kg was necessary to counterbalance the scopolamine-induced effect. Thus, 5-HT depletion decreased the efficacy of pilocarpine in reversing a scopolamine-induced spatial reference memory deficit. In another study, Riekkinen *et al.* (1991b) have reported that scopolamine (0.8 mg/kg, i.p.) and the 5-HT reuptake blocker alaproclate (7.5 and 20 mg/kg, i.p.) were able to impair water-maze navigation performance. Furthermore, the combined injections of scopolamine (0.8 mg/kg) and alaproclate (20 mg/kg) produced greater impairment than after only scopolamine treatment. This effect could

be partially reversed by administration of pilocarpine (6 mg/kg). A subamnesic dose of atropine has also been described to produce cognitive perturbations in rats given 5,7-DHT into the ventricles or directly into the fimbria-fornix, while sham-operated rats showed normal performance (Richter-Levin *et al.*, 1994).

Riekkinen *et al.* (1992) also demonstrated that nicotinic receptors may be involved in the cholinergic-serotonergic regulation of cognitive function. Indeed, this group has investigated the cognitive effects of mecamlamine (10 mg/kg, i.p.), a nicotinic antagonist, in rats subjected to massive 5-HT depletion (pCPA). The authors focused on passive-avoidance and water-maze performances. Neither performance was affected by pCPA treatment. Given alone in intact rats, mecamlamine delayed spatial learning in the water maze but did not affect passive avoidance. In pCPA-treated rats, however, mecamlamine induced a marked deficit in passive avoidance. Subsequently, Riekkinen *et al.* (1993) reported the results of a study in which they investigated the effects of mecamlamine (7.5 mg/kg, i.p.) in pCPA-treated rats on working memory in a water maze and on a passive-avoidance response. They confirmed that pCPA did not affect water-maze navigation or passive-avoidance performances, and showed that mecamlamine (slightly) impaired working memory and (substantially) altered passive-avoidance performances in intact rats. This effect was counterbalanced or attenuated by nicotine treatment (0.3 mg/kg, i.p.). In pCPA-treated rats, the mecamlamine-induced impairments were more pronounced and the preventive effect of nicotine was less marked than in intact rats. Riekkinen *et al.* (1994) reported that medial septal lesions impaired performance in both passive-avoidance and water-maze learning tasks. These deficits were aggravated following pCPA-induced 5-HT depletion, which, alone, left learning intact. Pre-training trial injections of tetrahydroaminoacridine (THA, 1, 3 and 5 mg/kg, i.p.), an acetylcholinesterase inhibitor, or nicotine (0.03, 0.1 and 0.3 mg/kg, i.p.) attenuated the deficit in rats with septal lesions at the respective doses of 3 mg/kg (THA), 0.1 and 0.3 mg/kg (nicotine) and in both tasks. In rats that had sustained both a septal lesion and 5-HT depletion, only THA was found to exert beneficial effects.

In some memory tasks, intact attention resources may be required to achieve optimal performance. Therefore, it is worth mentioning a possible implication of cholinergic-serotonergic interactions in attention processes. Using rats, Jäkälä *et al.* (1992) examined the effects of pCPA and/or scopolamine treatment on attentional processes measured in the five-choice serial reactional time test. This test measures the rats' ability to detect and respond to brief flashes of light presented in one of five food-rewarded locations. The authors found that scopolamine

(0.2 mg/kg, i.p.) did not alter the discriminative accuracy (proportion of appropriate locations detected among all responses) in the rats that did not sustain pCPA-induced lesions. Under standard test conditions (intensity of visual stimulus and speed of presentation fixed), the discriminative accuracy of pCPA-treated rats tended to decrease. Addition of scopolamine treatment did not further impair pCPA-treated rats. Only when stimulus intensity was reduced or speed of presentation increased did pCPA-treated rats show impaired accuracy. These observations suggest that part of the synergistic effects of 5-HT depletion and cholinergic blockade on memory performance might involve difficulties in attentional function. A weak behavioral effect of concurrent serotonergic and cholinergic manipulations has also been reported by Robinson *et al.* (1993) in a water-maze learning task, and thus on spatial reference memory processes. These authors induced long-lasting serotonergic depletion by treating rats with high doses of MDMA, and found that 5-HT-depleted rats performed similarly to intact control rats. In addition, MDMA-treated rats showed a sensitivity to systemically-administered atropine (50 mg/kg, i.p.) that did not differ from that of intact rats. Robinson and colleagues interpreted these weak effects as being due to insufficient depletion of cortical 5-HT (−73 percent in the neocortex, −32 percent in the caudate nucleus).

### ***Reversing the effects of cholinergic drugs by acting on 5-HT<sub>1A</sub> somatodendritic autoreceptors***

Although this approach may at first appear to be outside the scope of this chapter, it is noteworthy that the activation of 5-HT<sub>1A</sub> receptors in the raphe nuclei produces a transient reduction of the overall serotonergic tonus in regions such as the cortical mantle and the hippocampus. Therefore, the acute functional consequences of activation of these receptors can be paralleled with 5-HT depleting treatments (e.g., Invernizzi *et al.* 1991), and their interaction with treatments altering cholinergic functions will be briefly reviewed. In 1995, Carli and colleagues published the result of an experiment in which rats were trained in a two-platform spatial discrimination task after intrahippocampal infusions of scopolamine (Carli *et al.*, 1995). Most interestingly, the systemic injection of a relatively selective 5-HT<sub>1A</sub> receptor antagonist, namely WAY 100135, prevented this impairment, although not through action on the 5HT<sub>1A</sub> receptors located in the hippocampus, as the directly intrahippocampal infusion of WAY 100135 had no effect on the scopolamine-induced impairment. Later on, these effects were confirmed with a highly selective 5-HT<sub>1A</sub> receptor antagonist (Carli *et al.*, 1997), WAY 100635. These studies did not resolve the question

of which 5-HT<sub>1A</sub> receptors accounted for the observed effects, those located postsynaptically, or the somatodendritic ones located on the raphe neurons. This is partly why Carli and colleagues undertook an experiment in which they infused a 5-HT<sub>1A</sub> receptor agonist directly into the dorsal raphe (Carli *et al.*, 1998; see also Carli *et al.*, 2000). These authors elegantly demonstrated that the effects described in their 1995 and 1997 articles could be reproduced by activation of the somatodendritic 5-HT<sub>1A</sub> receptors of the raphe serotonergic neurons, and thus by transient reduction of the serotonergic tonus in the target regions of these neurons.

### Concluding remarks

Together, the results summarized in the third section of this chapter clearly show that 5-HT may modulate the efficacy of the basal forebrain cholinergic contribution to learning and memory functions. Indeed, acute (using drug treatments), semi-chronic (using pCA or pCPA) or permanent (using 5,7-DHT) alterations in serotonergic function may potentiate the effects on learning and memory of a drug- or lesion-induced cholinergic dysfunctioning within the septo-hippocampal or/and basolocortical systems. Here, the cholinergic system has been taken as one of the possible examples illustrating how changes in 5-HT levels may affect (reduce or enhance) the efficacy of other treatments targeting the cholinergic synapses or neurons. It is likely that interactions between the serotonergic system and other neurotransmitter systems might also have important implications in learning and memory functions. This could be the case, for instance, for GABAergic, glutamatergic, noradrenergic and dopaminergic systems (see, for example, Myhrer, 2003). Regarding the hippocampus, which plays a crucial role in cognitive functions, an idea of the complexity of the different modulating influences that may change serotonergic functions at simply a presynaptic level can be found in the excellent review by Vizi and Kiss (1998; see also Fink and Göthert, 2007).

### General conclusions

In the nervous system of invertebrates such as *Aplysia*, snails, worms, leeches, etc., 5-HT participates in the establishment of non-associative and associative memories. When the 5-HT system is disrupted, the generation of these types of memories is more difficult, or simply impossible. Contrarily, in at least some of these animals, increased 5-HT function may facilitate learning.

With regard to higher vertebrates such as rodents, although there is no consensus in the literature, the

implication of the ascending serotonergic systems in learning and memory functions might be summarized as follows: when these systems are damaged in a selective manner (such as is the case with 5,7-DHT), even when they are destroyed massively, this damage may have consequences on various aspects of a rat's or mouse's behavior (see, for example, Cools *et al.*, 2008), but learning and memory capabilities seem largely intact, except when lesions or pharmacological manipulations affecting other neurotransmitter systems are performed conjointly. This is true for most classical tests used in laboratories to explore the neurobiological and neuropharmacological substrates of learning and memory functions, and some results point to the fact that rats in which 5-HT has been depleted may show impairments in tasks which are taxing short-term memory. Serotonergic functions may also be pharmacologically enhanced – for instance, under the effects of MDMA or the influence of antidepressant drugs such as SSRIs. Based on a recent review that focused on the effects of antidepressant drugs on memory (Monleón *et al.*, 2008), SSRIs may have two types of effects depending on whether they are given before or after training. When administered before training, they leave memory functions either largely intact or altered, and may even improve them, but the latter case is very exceptional. When given after training, they have no effect on memory or they may improve it. Some of the variation among studies might be due to differences in the duration of the produced effects (acute, semi-chronic, permanent) and in the types of test and task used, as well as in the nature of serotonergic (for instance SSRIs may affect neurogenesis) or/and non-serotonergic (e.g., anticholinergic or 'pro'-noradrenergic) side effects of the various drugs tested so far. Furthermore, it cannot be excluded that factors such as species, strain and sex have also interfered with the outcome of the various experiments considered herein. From the experiments that have combined alterations of serotonergic functions with disruption of, for example, the cholinergic system – the example considered and documented to some extent in this chapter – it is relatively clear that the ascending serotonergic system cooperates with the cholinergic system in the modulation of learning and memory functions. Regarding the basal forebrain cholinergic system, the literature now provides a series of convincing arguments supporting this view, although the link between septo-hippocampal cholinergic functions and memory has been challenged over the past 15 years (for a review, see Parent and Baxter, 2004).

One of the aspects not considered in this chapter is the role in learning and memory of the 14 different types or subtypes of serotonergic receptors (Nichols and Nichols, 2008). Whereas in rats and mice overall functional modifications (depletion, stimulation) of the serotonergic system

have generally weak effects on learning and memory, alterations that affect particular receptor types or subtypes, sometimes only in a particular and restricted region of the brain, have been found to disrupt or to enhance cognition (see, for example, Meneses, 2003; King *et al.*, 2008). This is not the place to review all these receptors and describe their transductional characteristics or other functional specificities/involvement, especially as some of this information is provided in several chapters of the current handbook. Moreover, the task of reviewing the literature regarding the effects on learning and memory of the activation, blockade or genetic manipulation of each of these receptors appears Herculean.

The weak consequences on learning and memory of massive 5-HT depletion vs the sometimes extensive impairments induced by the manipulation of a given receptor (see, for example, Koenig *et al.*, 2008) may seem surprising, if not paradoxical. However, in a recent review Azmitia (2007) has reminded that 5-HT influences almost all biological processes in vertebrates, in which many functions are acting in a combination described as holistic. Why, then, has an overall lesion of the serotonergic neurons so little impact on memory, whereas the blockade or activation of a particular receptor may have dramatic consequences? It is impossible to provide a clear response to this question. Given the wide distribution of serotonergic terminals, and of receptors, in the brain of vertebrates, especially mammals, it is nevertheless tempting to speculate that one of the basic roles to which serotonergic neurons have evolved over the phylum is the maintenance of a given functional equilibrium among the different target structures of these neurons. Such a conception can be compared to a mechanism serving homeostasis, as stated by Azmitia (2007). Thus, overall functional adaptations of the serotonergic system could contribute to maintaining the brain's capability for elaborate normal operations despite variations of external or/and internal constraints (such as fatigue, stress, hunger, hyperthermia, effort, etc.) within a given range. Regarding learning and memory, such adaptations might occur conjointly in all serotonergic targets relevant to these functions. As long as the aforementioned overall equilibrium is maintained (which is the case when the serotonergic tonus is increased conjointly in all target structures, by, for example, a systemically given SSRI, or is depleted by, for example, a more or less extensive 5,7-DHT-induced lesion), most of the operations underlying cognition could remain possible. However, there might be at least two situations in which these operations may be compromised and thus memory dysfunctions emerge: when some of the other neurotransmitter systems undergo functional alterations in addition to the overall 5-HT dysfunction (such as after cholinergic

lesions or muscarinic blockade, for instance), or when the overall serotonergic equilibrium is disrupted, which may be the case after a specific action on a specific serotonergic receptor. The latter point of view is totally speculative, and although it is not in contradiction to the role of the serotonergic system as a regulator of brain homeostasis, it is certainly no more than a possible support to designing working hypotheses driving future experiments.

### Acknowledgements of Strasbourg

I would like to acknowledge the Centre National de la Recherche Scientifique, the University of Strasbourg, the Alexander von Humboldt Stiftung and the National Institute for Drug Abuse for their support for my serotonin-related research. Thank you also to Dr Anne Pereira de Vasconcelos, Lucas Lecourtier and Bruno Will for their critical reading of a first draft of this chapter, and their helpful comments.

# Social Behavior and Serotonin

Elif Aysimi Duman<sup>1</sup> and Turhan Canli<sup>\*,1,2</sup>

<sup>1</sup>*Department of Psychology, Stony Brook University, Stony Brook, New York*

<sup>2</sup>*Graduate Program in Genetics, Stony Brook University, Stony Brook, New York*

**Abstract:** Serotonin (5-hydroxytryptamine, 5-HT) is implicated in the regulation of a wide range of social behaviors, including interpersonal aggression. Earlier studies investigating the role of 5-HT in aggression relied on the measurement of levels of the 5-HT metabolite 5-hydroxyindoleacetic acid (5-HIAA), and in later animal studies applied sophisticated pharmacological manipulations. With advances in molecular genetic techniques, the field has recently begun to focus on the genetic basis of individual differences in aggression. This chapter reviews studies of genetically modified animals and of gene polymorphisms in humans, with a particular focus on receptor genes, and gene polymorphisms located within the serotonin transporter (*5-HTT*), monoamine oxidase A (*MAOA*) and tryptophan hydroxylase 2 (*TPH2*) genes. We will also highlight recent imaging genetics studies and interactions with other genes and environmental factors, in order to point to promising future research approaches on the effects of serotonin on social behavior.

**Keywords:** serotonin, aggression, serotonin transporter (5-HTT), monoamine oxidase A (MAOA), tryptophan hydroxylase 2 (*TPH2*), gene polymorphism.

## Introduction

Social neuroscience is one of the fastest growing areas of neuroscience, reflecting an increased interest in the neural underpinnings of complex behaviors of interacting individuals. These behaviors are shaped by both genetic and socio-environmental factors (Robinson *et al.*, 2008): genetic factors contribute to the structure and function of the brain, presumably including neural circuits that are relevant to social behavior, whereas socio-environmental factors shape an individual's behavior through encoded experiences and modifications in neural circuits. Through epigenetic and other mechanisms, socio-environmental factors can also regulate gene expression. Individual differences in social behavior may reflect the influence of common variations within genes that affect the neural circuitry underlying social behavior, as well as the influence of individuals' non-shared environment.

In this chapter, we will therefore focus on the role of genes and of common gene variants ('polymorphisms') associated with individual differences in social behavior. Because serotonin plays a central role in the regulation of social behavior, particularly aggression (see below),

we will therefore focus on serotonergic gene variants and their role in interpersonal aggression (the discussion of self-directed aggression is beyond the scope of this chapter), which is of considerable societal importance (World Health Organization, 2007), and is a trait that shows both genetic and social environmental contributions (Seroczynski *et al.*, 1999).

Interpersonal aggression can be conceptualized in different ways. In many non-human animal studies, interpersonal aggression is conceptualized in terms of the stimuli that provoke the aggressive act, such as territorial aggression (Moyer, 1968). In many human studies, interpersonal aggression is conceptualized in terms of impulsive (reactive, uncontrolled) versus instrumental (goal-oriented, controlled) aggression, which are mediated by dissociable neural systems (Nelson and Trainor, 2007). Progress is made in our understanding of genetic and socio-environmental factors in these various forms of aggression. Much of this understanding rests on the neurobiology of the serotonergic system, as discussed below.

## Serotonin and aggression

Serotonin (5-hydroxytryptamine, 5-HT) is a critical monoamine neurotransmitter of the central nervous system (CNS) that is produced mainly by the serotonergic

\*Corresponding author  
E-mail: turhan.canli@sunysb.edu

neurons found along the midline of the brainstem, from where it projects throughout the entire CNS (Jacobs and Azmitia, 1992). Raphe nuclei of the midbrain serve as a major source of serotonin in the forebrain, and send axons to various structures such as the hypothalamus, cortex, hippocampus, amygdala and striatum (Lucki, 1998). Due to its wide distribution throughout the CNS, serotonin is involved in the regulation of many physiological processes and behaviors, including aggression.

Evidence for a role of serotonin in aggression first came from studies measuring the main metabolite of serotonin, 5-hydroxyindoleacetic acid (5-HIAA). Most of these studies reported an inverse relationship between serotonergic activity and aggression, although this view has recently come under criticism (Olivier, 2004) because more recent data show that the relationship between serotonin levels and aggression varies with the type of aggression that is measured.

On the one hand, several studies have reported a negative correlation. For example, in mice, the turnover rate calculated from the 5-HT and 5-HIAA contents of *post-mortem* brain tissue is much lower in isolated aggressive individuals than it is in non-aggressive individuals (Giacalone *et al.*, 1968; Valzelli and Bernasconi, 1979). Human studies using peripheral measures of lumbar-punctured CSF 5-HIAA also suggest an inverse relationship between serotonin and aggression (Brown *et al.*, 1979; Kruesi *et al.*, 1990). These measures, however, were non-specific, as they were also correlated with other behavioral measures such as impulsivity, risk-taking behavior and suicidal tendencies (Kruesi *et al.*, 1990; Mann, 2003), suggesting that low levels of CSF 5-HIAA may be particularly relevant to impulsive forms of aggression. Indeed, this interpretation is supported by studies of dogs and non-human primates, which also reported negative correlations between CSF 5-HIAA levels and impulsive aggression (Higley *et al.*, 1996; Reisner *et al.*, 1996).

On the other hand, there is evidence for a *positive* correlation between serotonin and aggression, as has been reported between measures of CSF 5-HIAA levels and competitive aggression, which is used to attain higher social dominance (Higley *et al.*, 1996; Westergaard *et al.*, 1999). Thus, different forms of aggression may show opposite associations with serotonin levels.

Another important variable may be the state- versus trait-like properties of aggression. Van der Vegt and colleagues reported that, in rats, CSF 5-HIAA levels correlated positively with trait-like, but not with state-like, aggression (van der Vegt *et al.*, 2003). Of course, with regard to genetic mechanisms, one would search for genetic predictors of aggression particularly in trait-like phenotypes. Specific candidate genes that may impart individual differences in trait-like behavior will be discussed in the next section.

## Serotonergic candidate genes

Serotonin function in the CNS is regulated by proteins that are involved in its synthesis, degradation, transport and reception. Therefore, the search for candidate genes involved in aggression begins with those that play a central role in coding for these proteins. For example, serotonin is synthesized from the amino acid tryptophan in two steps: the first rate-limiting step catalyzed by the tryptophan hydroxylase (TPH) and the second step catalyzed by the aromatic *l*-amino acid decarboxylase. TPH is produced in two isoforms, encoded by two genes: one is *TPH1*, which is primarily expressed in the periphery and the pineal gland; the other is *TPH2*, which is primarily expressed in the CNS (Walther and Bader, 2003). Another example concerns the degradation of serotonin by the enzymes monoamine oxidase A and B, which are encoded by the X-linked *MAOA* and *MAOB* genes, respectively. *MAOA* is especially important in the degradation of serotonin following its reuptake from the synaptic cleft by the serotonin transporter (Craig, 2007). There is only one mechanism for the reuptake of extracellular serotonin, regulating serotonergic transmission and tone, which is accomplished by the serotonin transporter, encoded by the serotonin transporter gene (*5-HTT*, *SERT*) (Gainetdinov and Caron, 2003). Postsynaptically, serotonin binds to any of 14 serotonin receptor subtypes: 5-HT<sub>1A</sub>, 5-HT<sub>1B</sub>, 5-HT<sub>1D</sub>, 5-HT<sub>1E</sub>, 5-HT<sub>1F</sub>, 5-HT<sub>2A</sub>, 5-HT<sub>2B</sub>, 5-HT<sub>2C</sub>, 5-HT<sub>3</sub>, 5-HT<sub>4</sub>, 5-HT<sub>5A</sub>, 5-HT<sub>5B</sub>, 5-HT<sub>6</sub> and 5-HT<sub>7</sub>. Several of these receptors have been shown to influence aggressive behavior, as discussed in the following section.

## Serotonin receptors and aggression

The role of serotonin receptor subtypes in aggression has been mostly investigated in drug and genetic knockout mouse studies (Lesch and Merschdorf, 2000; Miczek *et al.*, 2002; Popova, 2006). One of these receptor subtypes is 5-HT<sub>1B</sub>, which was studied extensively in mouse models (Olivier and van Oorschot, 2005). 5-HT<sub>1B</sub> receptors are expressed in many brain regions, such as the raphe nuclei, periaqueductal gray, lateral septum, basal ganglia and hippocampus. 5-HT<sub>1B</sub> receptors can function as autoreceptors that inhibit serotonergic neuron firing and thus serotonin release, or as heteroreceptors that release other neurotransmitters. In an earlier study, Saudou and colleagues reported that 5-HT<sub>1B</sub> knockout mice exhibited more aggressive behaviors than controls (Saudou *et al.*, 1994), and this finding was also supported by pharmacological studies utilizing 5-HT<sub>1B</sub> agonists (Olivier and van Oorschot, 2005).

A role for 5-HT<sub>1A</sub> in aggression was documented in a study that compared 5-HT<sub>1A</sub> receptor levels across two

strains of mice: Korte and colleagues compared highly aggressive SAL male mice (who were genetically selected to exhibit short attack latencies to a non-aggressive opponent in a neutral cage) with low-aggression LAL mice, and reported that SAL mice were characterized by more postsynaptic 5-HT<sub>1A</sub> receptors in limbic and cortical regions (Korte *et al.*, 1996). However, this phenotype may not be specific to aggression, because the SAL mice were also characterized by low corticosterone levels and a general pattern of active behavioral stress responsiveness (Korte *et al.*, 1996). On the other hand, data from humans suggest the opposite pattern between 5-HT<sub>1A</sub> levels and aggression: evidence from pharmacological and positron emission tomography (PET) studies suggests an inverse relationship between questionnaire-assessed aggression and 5-HT<sub>1A</sub> receptor function and binding in various regions of the brain (especially in the orbital prefrontal cortex) (Cleare and Bond, 2000; Parsey *et al.*, 2002).

Another serotonin receptor that is associated with aggression is the 5-HT<sub>2A</sub> receptor, which is mainly found in the neocortex (Olivier, 2004). Antagonists of this receptor were shown to decrease aggressive behavior in rats and human clinical populations, although there are concerns that these effects are not aggression-specific, but rather act indirectly on aggressive behavior by altering locomotor activity (Miczek *et al.*, 2002). In humans, a recent human PET study (Meyer *et al.*, 2008) compared levels of 5-HT<sub>2A</sub> binding potential (an index of receptor density) in the prefrontal cortex of violent aggressive individuals with healthy controls. It was reported that there is a negative correlation between aggression and prefrontal 5-HT<sub>2A</sub> binding. Interestingly, this relation was only observed in younger subjects of the sample, and not in older subjects. Again, the association with aggression was confounded, because lower prefrontal binding was also associated with higher impulsivity scores.

Taken together, these studies suggest the involvement of 5-HT<sub>1A</sub>, 5-HT<sub>1B</sub> and 5-HT<sub>2A</sub> receptor subtypes in aggression across both animal and human studies, although it should be noted that there may be other neurotransmitter systems acting upon the serotonergic neurons to elicit these changes (Siever, 2008). Moreover, the available data illustrate that future studies of the serotonergic regulation of aggressive behavior need to be designed to assess the role of potential confounding variables, such as age and trait impulsivity.

### Serotonin transporter and aggression

The serotonin transporter, 5-HTT, enables the reuptake of excess serotonin from the synaptic cleft. The link to aggressive behavior has been demonstrated with

genetically modified knockout 5-HTT male mice, which were shown to have more extracellular 5-HT and exhibit less aggressive behavior, as measured by the latency and number of attacks towards an intruder, than did wild-type animals (Holmes *et al.*, 2002).

In non-human primates and in humans, a common polymorphism in the promoter region (5-HTTLPR) of the 5-HTT gene has been the subject of many association studies investigating personality traits and psychiatric disorders (Lesch, 2007; Schinka *et al.*, 2004). This polymorphism exists in the form of two alleles (there is additional evidence for a single nucleotide polymorphism (SNP) within one of these alleles): a short (*s*) and a long (*l*) variant. The presence of one or two copies of the short variant (*s*-carriers) is associated with lower mRNA transcription (Lesch *et al.*, 1996). With respect to aggressive behavior, the *s*-variant is associated with violence in male adults (Liao *et al.*, 2004; Retz *et al.*, 2004), as well as aggressive behavior in children (Davidge *et al.*, 2004).

The 5-HTTLPR polymorphism has also been shown to differentially moderate the effects of environmental factors, illustrating a gene-by-environment ( $G \times E$ ) interaction. For example, Barr and colleagues investigated the effects of early-life rearing conditions (mother- vs peer-reared) and *rh5-HTTLPR* genotype on aggression in juvenile macaque monkeys, as measured by bites, hairpulls, aggressive chases, hitting or slapping behaviors (Barr *et al.*, 2003). There was evidence for a  $G \times E$  interaction: in *sl/sl* individuals peer-rearing was associated with much more aggressive behavior than was mother-rearing, but in *ll/ll* subjects rearing condition did not differentially affect aggressive behavior. A similar  $G \times E$  interaction was observed in humans by Reif and colleagues, who reported that presence of the 5-HTTLPR short allele moderates the effects of childhood maltreatment on later aggressive behavior (Reif *et al.*, 2007).

Using self-report measures of life stress history, we found evidence for a  $G \times E$  interaction in the human brain (Canli *et al.*, 2006). High levels of life stress correlated positively with resting activation (as measured with perfusion imaging) in the amygdala and hippocampus in carriers of the *s*-allele, but correlated negatively in non-carriers. A similar pattern was recorded with fMRI during processing of emotional stimuli, and was observed in a wide range of brain regions involved in social behavior (Canli *et al.*, 2006; Canli and Lesch, 2007). We therefore speculated that 5-HTTLPR genotype and a history of life stress interact to differentially shape neural circuits that generate social behavior (including aggression) (Canli and Lesch, 2007), but an explicit test of this hypothesis remains to be conducted.

Although an individual's genotype and life history are *ex post facto*, and thus represent a vulnerability that

cannot be altered by therapeutic intervention, there is evidence that the current environment can ameliorate such vulnerability. For example,  $G \times E$  vulnerability may be reduced through social support, as is suggested by Kaufman *et al.* (2004) in a study of maltreated children. These investigators showed that maltreated children with the 5-HTTLPR short allele were more likely to become depressed than maltreated children who were homozygous for the long allele, but that this vulnerability could be significantly ameliorated if these children had social support in the form of a confidante. Future studies will hopefully address which kinds of social interventions are most successful in reducing the impact of adverse genetic and life history variables on later aggressive behavior. The discoveries from such studies would clearly be of broad scientific and public policy significance.

### MAOA and aggression

Of the two forms of monoamine oxidases (MAOA and MAOB), most of the literature has focused on MAOA due to its role as the principal enzyme in 5-HT degradation, and its links with various types of aggressive behavior (Shih *et al.*, 1997; Popova, 2006). Disruption of the MAOA gene in mice is associated with increased aggressiveness, as measured by the intruder paradigm, as well as decreased firing in 5-HT neurons (Cases *et al.*, 1995; Popova *et al.*, 2001). Although the MAOA knockout mice showed increases in both serotonin and norepinephrine, the observed behavioral changes such as increased male aggression were linked to decreased serotonin degradation (Cases *et al.*, 1995). None of these effects were observed in MAOB knockout mice (Shih *et al.*, 1997, 1999). Very striking analogous human data come from a Dutch family study, in which a rare point mutation resulted in a stop codon in the MAOA gene, leading to a functional modification that is comparable to a 'knockout'. This mutation was associated with behavioral abnormalities like impulsive aggression in 14 male members of the family through four generations (Brunner *et al.*, 1993).

In addition to knockout studies, a variable number tandem repeat (VNTR) polymorphism in the promoter region of MAOA (MAOA-LPR) was shown to interact with both 5-HTTLPR polymorphism and various environmental factors. This polymorphism results in 3, 3.5, 4 and 5 copies of this 30-bp sequence in the promoter region, leading to differential levels of expression of the gene and consequent differences in enzymatic activity. Accordingly, gene variants are classified as either low-activity (three- and five-repeat alleles) or high-activity alleles (Sabol *et al.*, 1998). The low-activity alleles were associated with reduced aggression in a community sample of males,

as measured by the Aggression/Impulsivity (AI) index (Manuck *et al.*, 2000).

Non-human primate studies considering the orthologous MAOA VNTR polymorphism in rhesus monkeys (*rhMAOA-LPR*) have suggested that this polymorphism interacts with early life experiences (mother-reared or not) to regulate aggressive behavior. For example, Newman *et al.* (Newman *et al.*, 2005) investigated the role of MAOA genotype and rearing experience on aggressive behavior during competition for food and during social interactions in male rhesus monkeys. Whereas there was no main effect of either genotype or rearing condition on aggression, there was evidence for a  $G \times E$  interaction: the most aggressive individuals were those who were reared by their mother and who also carried the low-activity *rhMAOA-LPR*. In contrast, animals with the same genotype who were reared by peers were less involved in aggressive behaviors, and did not differ significantly from mother-reared individuals with the high-activity allele (Newman *et al.*, 2005). This result is surprising, in light of data from *rh5-HTTLPR* and macaques (reviewed in the previous section) that suggest lower levels of aggression in genetically vulnerable individuals if they are reared by their mother. Newman and colleagues suggest that the higher level of aggression seen in mother-reared low-activity *rhMAOA-LPR* monkeys may be adaptive, because the ability to show aggression in competitive social interactions is important for monkeys to obtain a higher rank in their social group. This argument may be valid, but could be equally applied to the *rh5-HTTLPR* data, and thus does not resolve the apparent contradiction. Yet the notion that aggression is not necessarily ill-adaptive is important, and future work could benefit from operationalizing the utility of aggression and measuring the influence of  $G \times E$  interactions with respect to the adaptivity of aggressive behavior, rather than simply the extent of displayed aggressive behavior.

The first study to demonstrate any specific  $G \times E$  interaction in humans was conducted by Caspi and colleagues, (Caspi *et al.*, 2002) in which the authors reported that the effect of childhood maltreatment on later development of antisocial behavior is moderated by the MAOA-LPR genotype. Maltreated children (all males in this study) with the low-activity variant of MAOA were more likely to show antisocial behavior than the ones with the high-activity variant. A replication study by Reif and colleagues also found an interaction between presence of the low-activity variant of MAOA and adverse childhood environment predicting violent behavior, but also identified significant main effects for both of these variables (Reif *et al.*, 2007). Other studies demonstrated that the interaction between MAOA genotype and childhood maltreatment influence the risk for both aggression and impulsive

behavior in general (Caspi *et al.*, 2002; Huang *et al.*, 2004), an observation that was confirmed by a recent meta-analysis (Kim-Cohen *et al.*, 2006). These results suggest that the low-activity variants of the *MAOA* gene render individuals vulnerable towards an aggressive phenotype.

Another variable that may moderate the association between *MAOA* and aggression is the individual's sex. It was suggested that sex differences are not merely a result of *MAOA* being X-linked, but are also due to the different effects of sex hormones in males and females (Buckholtz and Meyer-Lindenberg, 2008). For example, it was reported that in rhesus monkeys, estrogen receptors are involved in regulating *MAOA* transcription in amygdala, anterior cingulate cortex (ACC) and orbitofrontal cortex (OFC), which are implicated in emotion regulation and partly in aggression (MacLusky *et al.*, 1986). Considering the significant sex differences in the expression of aggressive behaviors, the mechanisms by which sex hormones moderate the impact of *MAOA* on aggressive behavior will likely be a fruitful area of future work.

Genetic variation in *MAOA* and *5-HTT* may play an additive role in contributing to an aggressive phenotype. Wendland and colleagues noted that macaque species differ in their degree of tolerance with each other and with respect to hierarchical structures. Tolerant macaque societies were characterized by monomorphic *MAOA* and *5-HTTLPR* genotypes, whereas intolerant and hierarchical macaque societies were polymorphic at one or more of these loci (Wendland *et al.*, 2006). An explicit test of this hypothesis remains to be conducted.

The mechanism by which *MAOA* and *5-HTT* could both contribute to an aggressive phenotype may involve genetic regulation of the same neural circuitry. Indeed, recent imaging genetics studies (for a review and commentary, see Buckholtz and Meyer-Lindenberg, 2008) highlight the importance of *MAOA* and *5-HTT* on brain function. The low-activity variant of the *MAOA* was reported to increase amygdala and insula activation towards emotional facial stimuli, and decrease the involvement of PFC in emotion regulation (through OFC and ACC) (Meyer-Lindenberg *et al.*, 2006). Furthermore, impulsive aggressive individuals show decreased *5-HTT* availability in the ACC, compared to controls (Frankle *et al.*, 2005), suggesting that modulation of serotonin levels in the ACC by either *MAOA* or *5-HTTLPR* variation may contribute to individual differences in ACC regulation of limbic regions, and potential dysregulation leading to impulsive aggression.

### TPH2 and aggression

Tryptophan depletion studies have long pointed to a role for TPH in human aggressive behavior (Moeller *et al.*,

1996; LeMarquand *et al.*, 1998; Dougherty *et al.*, 1999; Marsh *et al.*, 2002). More recently, the *TPH2* gene was shown to contain various polymorphisms (Rotondo *et al.*, 1999), one of which (C779A) was associated with individual differences in CSF 5-HIAA levels (Nielsen *et al.*, 1994, 1998), which in turn have been linked to impulsivity and impulsive aggression (see above). More direct evidence for a role in aggression comes from an animal study in which an SNP in *Tph2* (C1473G) was shown to affect the enzymatic activity in mice and was associated with aggressive behavior. Mice that were homozygous for the C allele had higher *Tph2* activation in the midbrain than did mice that carried the G allele. The C/C mice also displayed higher levels of intermale aggression, as measured by the frequency of attacks towards an intruder, compared to mice that were homozygous for the G allele (Kulikov *et al.*, 2005).

Another SNP in the upstream regulatory sequence of *TPH2* (G703T) was recently associated with differential response in the amygdala towards both positive and negative emotional face stimuli (Brown *et al.*, 2005; Canli *et al.*, 2005). Using fMRI, our group reported that the presence of the T allele is associated with increased amygdala activation towards both happy vs neutral and fearful and sad vs neutral faces (Canli *et al.*, 2005). Using three different experimental paradigms (emotional picture perception, face perception, and an emotional word Stroop task) and two different brain activation measures (event-related potentials (ERPs) and fMRI), we and our collaborators reported additive effects of the *5-HTTLPR* polymorphism and *TPH2* G703T polymorphism in a sample of healthy volunteers (Herrmann *et al.*, 2007; Canli *et al.*, 2008). In both studies, subjects were divided into groups according to their *5-HTT* (*s*-carrier vs non-carrier) and *TPH2* (T-allele-carrier vs non-carrier) genotypes. The ERP study found that individuals who carried both of the gene variants that were associated with greater emotional reactivity (relative to a neutral control condition), i.e., the *s*-allele of *5-HTTLPR* and the T-allele of the *TPH2* polymorphism, showed the greatest neural activation of any group in response to emotional, compared to neutral, images (Herrmann *et al.*, 2007). The fMRI study found a similar pattern of activation in those who carried both the *s*-allele of *5-HTTLPR* and the T-allele of the *TPH2* polymorphisms, compared to all other individuals, when measuring brain activation in the putamen and amygdala in response to emotional faces and words (Canli *et al.*, 2008). These studies illustrate the additive effects of *5-HTT* and *TPH2* gene polymorphism in an individual's response towards emotional stimuli. At this time, an additive effect in impulsive aggression, or other forms of aggression, remains to be evaluated.

## Concluding thoughts

In this chapter, we have reviewed the evidence for a role of the serotonergic system in different types of aggression. We integrated data from behavioral, genetic and neuroimaging studies, and highlighted the role for  $G \times E$  interactions. To better understand the genetic contributions to individual differences in aggression, we highlighted studies that illustrate how polymorphisms within genes that play an important role in the synthesis, regulation or breakdown of serotonin have been associated with different forms of aggressive behavior. Moving towards more explicit mechanisms underlying  $G \times E$  interactions, we discussed evidence for interactions between these gene polymorphisms and environmental factors, as in the case of *MAOA* and *5-HTT* interacting with adverse childhood environment. We discussed imaging studies that show associations between these genetic variations or  $G \times E$  interactions and individual differences within neural circuits involved in the processing of emotional stimuli or involved in emotion regulation.

The reviewed literature illustrates how individual differences in social behavior can be traced to specific candidate genes, genetic variations, gene–gene additive effects, and  $G \times E$  interactions, which are associated with individual differences in neural circuits that regulate social behavior. Future efforts will need to be directed at the underlying causal mechanisms by which genetic and environmental variables interact with each other, and how these interactions alter the structural and functional features of neural circuits. One likely candidate mechanism by which environmental factors interact with genes involves epigenetic alterations that modulate gene expression without altering the DNA sequence itself. The power of epigenetic regulation through social experience was first illustrated in the case of rat maternal care affecting both the offsprings' stress responses and the associated methylation of the glucocorticoid receptor gene (Weaver *et al.*, 2004). Intriguingly, a similar pattern has now been reported in human brains. McGowan and colleagues compared *post-mortem* brain tissue from suicide victims with a history of childhood abuse, no abuse, and controls, and found differential methylation in a promoter region of the glucocorticoid receptor gene as a function of history of childhood abuse (McGowan *et al.*, 2009).

As we advance our understanding of the mechanisms by which biological and environmental variables interact to shape social behavior, there will likely be strong interest in applying this knowledge to social policy. For example, reliable and accurate prediction of aggressive behavior would be relevant in the judicial system for parole decisions. Appropriate courses of punishment, treatment or interventions for juvenile delinquents or domestic abusers

might be informed by a better understanding of any individual offender's genetic and life-history profile. Scientific discoveries could – indeed should – come to bear in these kinds of scenarios, with the goal of improving existing solutions. This is not to say that science can solve all social ills, or that scientific discoveries are around the corner that can deliver such accurate predictions. Indeed, one increasingly important duty of scientists should be to temper public expectations and a rush towards public policy applications based on preliminary findings. However, in times of social upheaval, understanding the mechanisms that explain individual differences in social behavior is a worthwhile effort with eventual significant public policy implications, if pursued with scientific rigor and public support.

# Serotonin in Pain and Pain Control

Claudia Sommer\*

*Department of Neurology, University of Würzburg, Germany*

**Abstract:** In pain processing and modulation, serotonin (5-hydroxytryptamine, 5-HT) has excitatory (hyperalgesic) and inhibitory (analgesic) actions, depending on the site of action, the cell type and the type of receptor. In the periphery, 5-HT sensitizes afferent nerve fibers, thus contributing to inflammatory and neuropathic hyperalgesia. In the trigeminal system, agonism at 5-HT<sub>1B/D</sub> receptors reduces neurotransmitter release, whereas actions through the 5-HT<sub>2A</sub> receptor may underlie chronic headache. Genetic alterations in the 5-HT system may influence the susceptibility to migraine and to other pain disorders. 5-HT is involved in descending inhibitory pathways in the CNS, and modulation of this system is the most likely mechanism of action of antidepressant drugs in analgesia. Recently, facilitatory serotonergic pathways have been discovered, which may be functionally important.

**Keywords:** serotonin (5-HT), pain, hyperalgesia, neurotransmitters, pain pathways, inflammation.

## Introduction

The effect mediated by 5-HT release is dependent on the cell and receptor type the neurotransmitter acts upon, and on the integration of the signal into the respective neuronal network. The classical understanding of serotonin is that of an analgesic action at spinal sites, which is considered part of the system of descending inhibition (Yaksh and Wilson, 1979). Strengthening this system, together with noradrenergic descending pathways, is the most likely mechanism of action of antidepressant drugs in pain control. Many experimental studies have further shown an interaction of the serotonergic system and morphine analgesia. Recently, facilitatory spinal serotonergic pathways have also been described (Suzuki *et al.*, 2004a). In peripheral tissues, 5-HT acts as a proalgesic inflammatory mediator (Moalem *et al.*, 2005). A specific role for 5-HT has been discussed in the pathophysiology of several types of headache (in particular migraine) and facial pain, of the fibromyalgia syndrome, and in neurogenic inflammation. For instance, 5-HT acting on 5-HT<sub>1B/D</sub> receptors in the trigeminal system blocks the release of excitatory neurotransmitters and is analgesic. Down-regulation of 5-HT receptors is considered one of the pathomechanisms of medication-induced headache. This chapter will review the physiology of 5-HT in pain and analgesia, and summarize the evidence for a role of 5-HT in specific painful disorders.

## Basic physiology of serotonin in pain and pain control

### 5-HT in the periphery

#### *Findings in animal models*

The 5-HT tissue content increases rapidly in inflammation or injury. The main cellular sources of 5-HT in peripheral tissues are platelets and mast cells. After release of 5-HT, its action depends on the receptors present on afferent nerves in the vicinity (Figure 1). The mRNA for the 5-HT<sub>1B</sub>, 5-HT<sub>1D</sub>, 5-HT<sub>2A-C</sub>, 5-HT<sub>3</sub>, 5-HT<sub>4</sub> and 5-HT<sub>7</sub> receptor subtypes has been detected in dorsal root ganglia (DRG) (Pierce *et al.*, 1996; Nicholson *et al.*, 2003), suggesting the presence of all these receptors on peripheral sensory nerves. However, which receptors are preferentially expressed may depend on various factors. For example, in isolated DRG neurons, stimulation of 5-HT<sub>1</sub> receptors had a hyperpolarizing effect, whereas stimulation 5-HT<sub>2</sub> receptors had a depolarizing effect on nociceptors (Todorovic and Anderson, 1992).

In most preparations, 5-HT was more potent in enhancing algesic effects of other mediators than in inducing pain by itself (Lang *et al.*, 1990; Abbott *et al.*, 1996). In rats, intradermally injected serotonin produces a dose-dependent hyperalgesia with a very short latency, indicating a direct excitatory effect on primary afferent neurons. This hyperalgesia can be mimicked by agonists for the 5-HT<sub>1A</sub> receptor (Taiwo and Levine, 1992). Application

of 5-HT to nerve roots in rats induced short-term pain behavior similar to that with nucleus pulposus application, suggesting that 5-HT plays a role in the early phase of the pathogenesis of sciatica (Kato *et al.*, 2008). Thus, direct hyperalgesic effects as well as facilitatory effects of 5-HT for other peripheral mediators are possible.

In mice lacking the serotonin transporter 5-HTT, which is necessary for 5-HT reuptake into cells from the extracellular space (Bengel *et al.*, 1998), thermal hyperalgesia after nerve injury does not develop, most likely because of the reduced 5-HT levels in peripheral tissues of these mice (Vogel *et al.*, 2003). A similar reduction of thermal hyperalgesia was found in a model of inflammatory pain using complete Freund's adjuvant (CFA) injection into the mouse hindpaw (Palm *et al.*, 2008). 5-HT levels were increased after inflammation in the sciatic nerves of wild-type mice but not of 5-HTT knockout mice. The phenotype could be rescued by intraplantar injection of 5-HT, giving proof of the role of peripheral 5-HT in this model. In both models, chronic constriction injury (CCI) of the sciatic nerve and CFA-induced inflammation, the development of thermal hyperalgesia was dependent on an increase of 5-HT in the sciatic nerve. This finding may be of clinical relevance, since gene variants in humans modifying 5-HTT function might be one of the factors determining the extent of hyperalgesia in inflammation. Genetic variants are also known for guanosine triphosphate (GTP) cyclohydrolase, the rate-limiting enzyme for tetrahydrobiopterin synthesis, which is a cofactor for serotonin production, among others (Tegeder *et al.*, 2006).

A haplotype leading to low tetrahydrobiopterin synthesis is associated with reduced postoperative and experimental pain.

The 5-HT<sub>3</sub> receptor, a ligand-gated cation channel, is the most widely studied 5-HT receptor in the concept of peripheral pain and analgesia (for review, see Sommer, 2004). Other investigators have identified 5-HT<sub>1</sub> and 5-HT<sub>4</sub> as the receptors involved in nociceptive behavior in formalin-induced paw inflammation in the rat (Eschalier *et al.*, 1989; Doak and Sawynok, 1997). 5-HT<sub>3</sub> receptor antagonists applied subcutaneously reduced formalin and complete Freund's adjuvant (CFA) induced pain (Giordano and Dyche, 1989; Giordano and Rogers, 1989). Pain but not edema in carrageenin-induced inflammation was blocked by preventive treatment with a 5-HT<sub>3</sub> antagonist (Eschalier *et al.*, 1989). Repeated injection of 5-HT into rat masticatory muscle evoked brief afferent fiber discharges, which could be significantly attenuated by the selective 5-HT<sub>3</sub> receptor antagonist tropisetron (Sung *et al.*, 2008). 5-HT, through activation of peripheral 5-HT<sub>3</sub> receptors, thus excites slowly conducting masticatory muscle afferent fibers. Similar mechanisms might contribute to 5-HT-evoked muscle pain in humans. In mice deficient in 5-HT<sub>3</sub> receptors, assays for acute pain, phase 1 of the formalin test, and tests for hyperalgesia and allodynia after partial nerve lesion gave normal results, but pain behavior in phase 2 of the formalin test was reduced, indicating a role of the 5-HT<sub>3</sub> receptor in tissue-injury-induced persistent nociception (Zeitz *et al.*, 2002). Furthermore, the visceral response to intraperitoneal

5-HT was reduced in the mutant mice. In the setting of CFA-induced hindpaw inflammation, the 5-HT<sub>3</sub> receptor was found to mediate activation of nociceptors but did not contribute to injury-associated edema. This result was explained by the distribution of 5-HT<sub>3</sub> receptor in DRG neurons in a minority of neurons of all sizes, the majority of which do not coexpress substance P or the vanilloid receptor TRPV1, thus defining a new subclass of DRG neurons (Zeititz *et al.*, 2002). Thus, the 5-HT<sub>3</sub> receptor is an important, but not the only, receptor mediating the peripheral analgesic action of 5-HT.

A number of experimental studies point to an important role of the G-protein-coupled 5-HT<sub>2</sub> receptor in peripheral 5-HT-mediated pain. 5-HT<sub>2</sub> receptors are expressed in CGRP-containing small-diameter DRG neurons. They are upregulated in inflammatory pain, and a 5-HT<sub>2A</sub> receptor antagonist reduces inflammatory hyperalgesia (Okamoto *et al.*, 2002). 5-HT<sub>2</sub> agonists injected into the plantar surface of the paw in rats induced lifting and licking, which was greatly enhanced in combination with prostaglandin E<sub>2</sub> and noradrenalin, and could be inhibited by the 5-HT<sub>2A/2C</sub> antagonist ketanserin (Abbott *et al.*, 1996). The density of 5-HT<sub>2A</sub> receptor immunoreactive axon terminals in the superficial layers of the dorsal horn was increased in vincristine neuropathy. Furthermore, 5-HT<sub>2A</sub> knockout mice did not develop neuropathic pain after vincristine administration, indicating that 5-HT<sub>2A</sub> receptors are involved in peripheral sensitization and spinal nociceptive processing (Thibault *et al.*, 2008). Injection of 5-HT and of the 5-HT<sub>2A</sub> receptor agonist alpha-methyl 5-HT reduced the paw-withdrawal latency to noxious heat in rats, indicating a role of the 5-HT<sub>2A</sub> receptor in thermal hyperalgesia (Tokunaga *et al.*, 1998). Treatment with 5-HT<sub>2A</sub> antagonists reduced the pain response in rats injected with formalin and carrageenan (Abbott *et al.*, 1997; Obata *et al.*, 2000; Wei *et al.*, 2005). Mechanistically, it has been suggested that activation of 5-HT<sub>2</sub> receptors depolarizes capsaicin-sensitive DRG neurons by reducing a resting potassium conductance, which might contribute to excitation and sensitization (McMahon *et al.*, 2006).

5-HT<sub>4</sub> receptors have been shown to increase tetrodotoxin-resistant sodium currents via stimulation of cyclic AMP production (Cardenas *et al.*, 1997, 2001). This would increase the probability of action potential firing, and thus be proalgesic. 5-HT<sub>4</sub> receptor agonists have been mostly discussed in the context of treating irritable bowel syndrome (Tonini and Pace, 2006) and in the prevention of opioid-induced respiratory depression (Manzke *et al.*, 2003; Lötsch *et al.*, 2005). The 5-HT<sub>7</sub> receptor has also been implied in peripheral hyperalgesia. Local administration of 5-HT<sub>7</sub> antagonist reduced formalin induced flinching in phase 1 and phase 2 (Rocha-Gonzalez *et al.*, 2005).

The activation of 5-HT<sub>1B/D</sub> receptors on trigeminal afferents inhibits adenylate cyclase via activation of G<sub>i/o</sub> proteins. 5-HT<sub>1B/D</sub> agonists (called triptans), such as sumatriptan and others, act on 5-HT<sub>1B/D</sub> receptors and inhibit neuropeptide release from the terminals of these afferents (Arvieu *et al.*, 1996). Sumatriptan also prevented capsaicin-induced hyperemia, a sign of neurogenic inflammation (Zochodne and Ho, 1994). Furthermore, sumatriptan reduced thermal hyperalgesia in mice with peripheral inflammation, but had no effect on nerve-injury-induced hyperalgesia (Bingham *et al.*, 2001). In summary, the majority of data point to a proalgesic action of 5-HT in the periphery at most receptors, with the exception of agonists at the 5-HT<sub>1B/D</sub> receptor, which may reduce neurogenic inflammation.

#### *5-HT agonists and antagonists in human studies*

In healthy volunteers, 5-HT infused into muscle did not induce pain or hyperalgesia by itself, but sensitized the tissue to bradykinin (Babenko *et al.*, 2000). 5-HT administered through intradermal microdialysis membranes produced pain and sometimes itching (Lischetzki *et al.*, 2001; Schmelz *et al.*, 2003). Injections of 5-HT into the masseter muscle in healthy human females induced pain and hyperalgesia which could be antagonized by a 5-HT<sub>3</sub>-antagonist (Ernberg *et al.*, 2000, 2006). Topical application of the 5-HT<sub>3</sub> receptor antagonist ondansetron reduced capsaicin-induced pain and hyperalgesia in human volunteers (Giordano *et al.*, 1998). In contrast, the application of 5-HT<sub>3</sub> receptor antagonists locally in humans with fibromyalgia or similar pain states gave equivocal results (Ernberg *et al.*, 2003; Stratz and Müller, 2003).

#### *Mechanisms of 5-HT actions on nociception in the periphery*

The neuronal mechanism of this pain and hyperalgesia were investigated in *in vitro* preparations of peripheral nerves. In these preparations, 5-HT has an excitatory effect on peripheral nerve fibers. Some investigators used a mixture of inflammatory mediators ('inflammatory soup') (Kessler *et al.*, 1992), and found ectopic excitation and sensitization of acutely axotomized afferent nerve fibers in the rat (Michaelis *et al.*, 1997). In DRG neurons in culture, 5-HT alone had no major effect, but a proton-induced current was increased by the combination of 5-HT with other inflammatory mediators (Kress *et al.*, 1997).

Recently, the selective administration of 5-HT and a 5-HT<sub>3</sub> receptor agonist has also been shown to sensitize C fibers in isolated segments of rat sural nerve (Moalem *et al.*, 2005). The characteristics of this sensitization were not altered after previous nerve injury, which led the

authors to conclude that constitutive rather than inducible expression of axonal 5-HT receptors is responsible for this effect. Others provided indirect evidence that 5-HT may have a stronger effect on lesioned or inflamed tissues and peripheral nerve fibers than on intact ones (Aley *et al.*, 2000; Song *et al.*, 2003).

Direct and indirect mechanisms of action have been postulated for the peripheral hyperalgesic action of 5-HT. 5-HT modulates tetrodotoxin-resistant (TTX-R) sodium currents, where it increases the magnitude of the current, shifts its conductance–voltage relationship to a hyperpolarized direction, and increases its rate of activation and inactivation (Gold *et al.*, 1996). The 5-HT<sub>3</sub> receptor, itself a ligand-gated ion channel, might directly enhance neuronal activity. Since 5-HT can sensitize nerve fibers to the actions of bradykinin, an effect on bradykinin receptors might be expected. Alternatively, downstream signaling of the mediators might converge and mutually enhance the effects. Protein kinase A (PKA) was identified as a factor in the signaling cascade of 5-HT after its intraplantar injection (Aley and Levine, 1999), and NO was suggested to facilitate this process, in analogy to findings with PGE<sub>2</sub> (Aley *et al.*, 1998). In an extensive pharmacological study, 5-HT-induced hyperalgesia was significantly reduced by local blockade of the 5-HT<sub>3</sub> receptor by tropisetron, by the non-specific selectin inhibitor fucoidan, by the cyclooxygenase inhibitor indomethacin, by guanethidine depletion of norepinephrine in the sympathetic terminals, and by local blockade of the beta<sub>1</sub>- or beta<sub>2</sub>-adrenergic receptors. The authors concluded that there is an indirect hyperalgesic action of 5-HT, mediated by a combination of mechanisms involved in inflammation such as neurophil migration and the local release of prostaglandin and norepinephrine (Oliveira *et al.*, 2007).

### **5-HT in the central nervous system**

#### *Data from animal experiments*

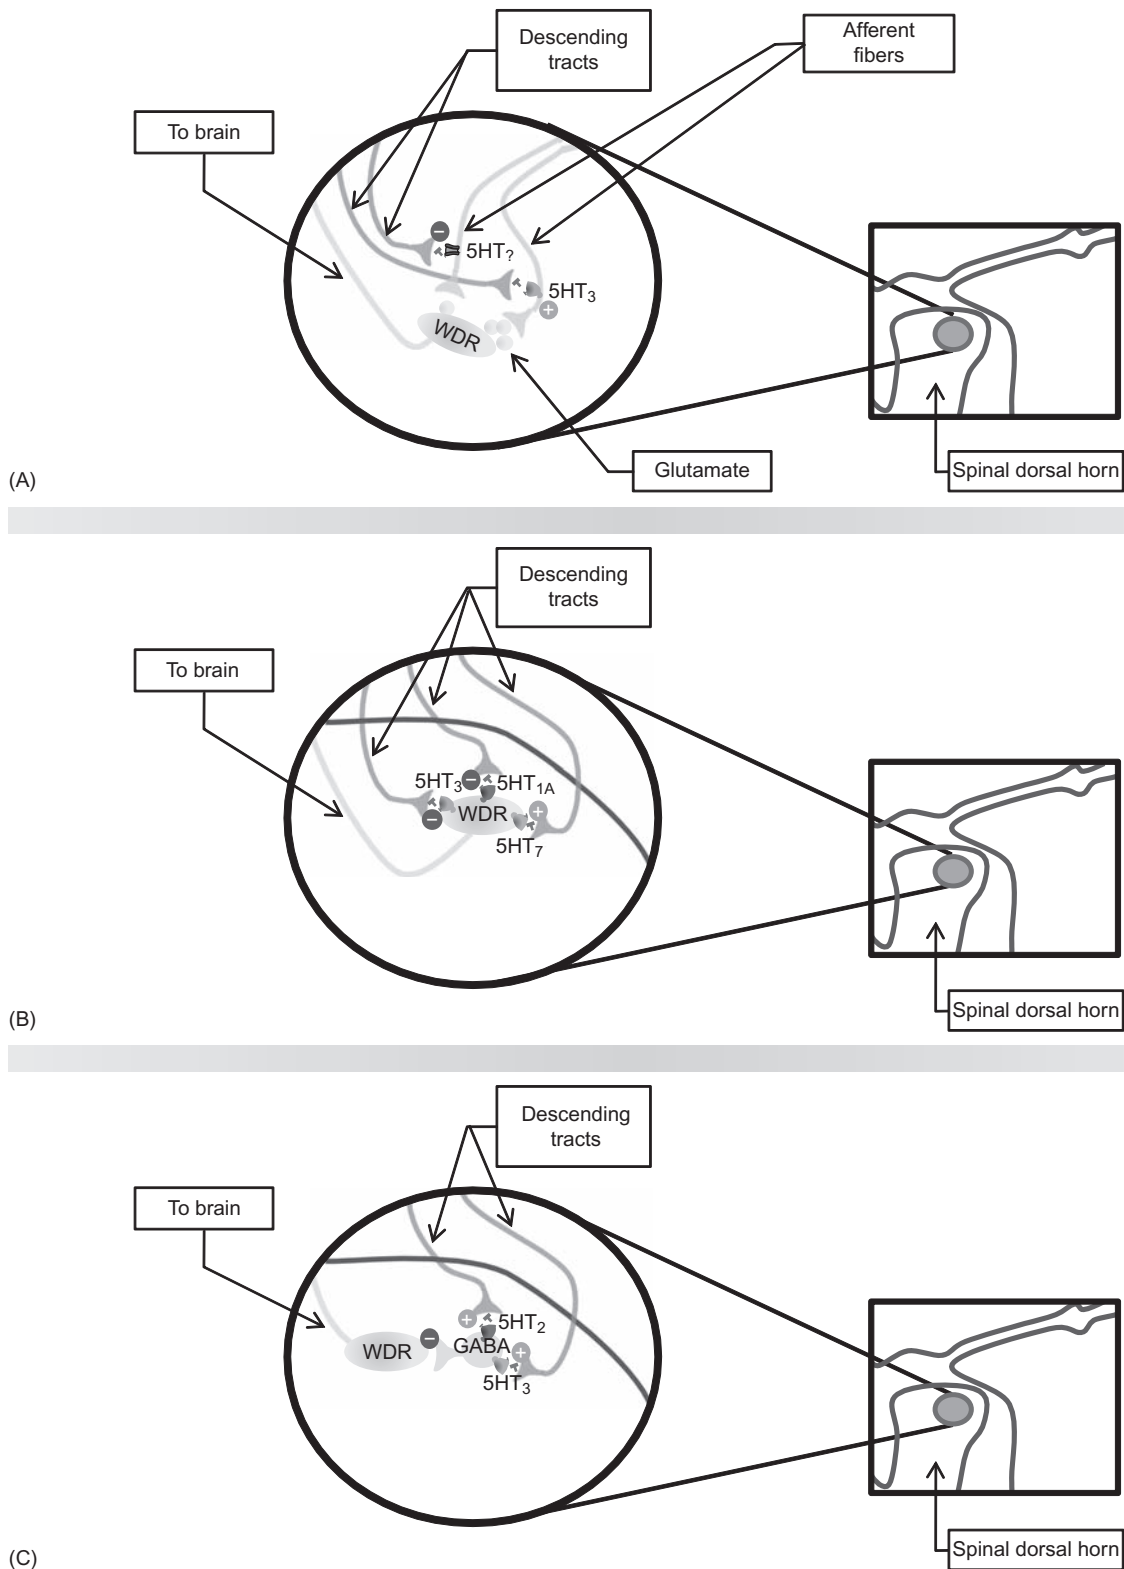

Numerous studies have been performed to delineate the role of 5-HT in central pain processing. A variety of approaches were used, including methods to reduce 5-HT levels in the CNS (like dietary tryptophan depletion or inhibition of serotonin biosynthesis, to block or activate 5-HT receptors) and selective lesions of serotonergic projections. Through many experimental studies, 5-HT has been recognized, together with norepinephrine, as one of the main neurotransmitters involved in endogenous supraspinal pain-modulating systems (Basbaum and Fields, 1978). This is in accordance with the clinical use of drugs increasing the availability of 5-HT and norepinephrine, like antidepressants, in the treatment of chronic

pain. However, excitatory effects of spinal 5-HT have repeatedly been described, and have to be integrated into our understanding of the serotonergic system (Figure 2).

*Spinal* 5-HT is largely derived from serotonergic neurons in the rostroventral medulla (RVM), in particular in the nucleus raphe magnus (NRM). Serotonergic tracts descend to the spinal cord through the dorsolateral funiculus and form synapses in laminae I, II, IV and V (Millan, 2002). The serotonergic RVM neurons are activated by noxious stimuli through opioid mechanisms (Zhang *et al.*, 2000). Their electrical stimulation evokes the release of 5-HT in the spinal cord cerebrospinal fluid, and 5-HT antagonists reduce the analgesia produced by this stimulation (Le Bars and Villanueva, 1988). In slice experiments containing RVM, some raphe neurons exhibit spontaneous firing, suggesting that 5-HT is released tonically onto the dorsal horn neurons (Yoshimura and Furue, 2006). Chronic pain states may reduce 5-HT in RVM neurons, thus reducing endogenous pain control and the effect of morphine (Sounvoravong *et al.*, 2004).

Stimulation of RVM or injections of 5-HT-receptor agonists into the spinal cord have shown both inhibitory and facilitatory effects on the pain behavior in animals. Electrophysiological studies showed an inhibition of the response of dorsal horn neurons to noxious stimulation when 5-HT was applied by iontophoreses (Duggan and Headley, 1977; Jordan *et al.*, 1978). Spinal administration of 5-HT mostly reduces pain behavior in animals, but results depend on the stimulus quality and the test used (Bardin *et al.*, 1997; Hains *et al.*, 2003). The antinociceptive activity of 5-HT is generally weak in models of neuropathic and inflammatory pain (Bardin *et al.*, 1997; Obata *et al.*, 2001). Excitatory effects have also been reported, mediated via 5-HT<sub>7</sub> receptors (Rocha-Gonzalez *et al.*, 2005), and possibly caused by increases in cyclic AMP levels, which shifts the voltage dependence of the cation current to more depolarized potentials and thus increases neuronal excitability (Cardenas *et al.*, 1999).

In the spinal cord, 5-HT receptors are present on terminals of primary afferent neurons, on projection neurons, and on excitatory and inhibitory interneurons, which makes the action of 5-HT very complex. Accordingly, blockade or depletion of spinal 5-HT can enhance nociception (Millan *et al.*, 1997; Pertovaara *et al.*, 2001). Excellent reviews on this subject have been published recently (Millan, 2002; Suzuki *et al.*, 2004b; Lopez-Garcia, 2006; Yoshimura and Furue, 2006). In particular, 5-HT<sub>2A</sub> and 5-HT<sub>3</sub> receptors, among others (Hamon and Bourgoin, 1999; Nicholson *et al.*, 2003), are expressed by primary afferent fibers that convey nociceptive messages from the periphery to the CNS (Hamon *et al.*, 1989; Carlton and Coggeshall, 1997). 5-HT presynaptically

**Figure 2** Simplified schematic drawing of the 5-HT descending system in the spinal cord. To see the full color version of this figure please refer to the color plate in the back of the book. Copies produced via our print on demand service do not contain color plates. If your copy does not have the color plate, Please go to this website to view the figure in color [www.elsevierdirect.com/companions/9780123746344](http://www.elsevierdirect.com/companions/9780123746344)

inhibits the glutamate release from nociceptors, but the receptor responsible for this effect has not yet been identified (Ito *et al.*, 2000). 5-HT<sub>1A</sub> and 5-HT<sub>1B</sub> receptors are present at high densities in superficial dorsal horn neurons, for example on nociceptive-specific or on wide dynamic range (WDR) neurons. 5-HT<sub>1A</sub> receptors, when activated, cause opening of K<sup>+</sup> and a closing of Ca<sup>2+</sup> channels through coupling negatively to adenylate cyclase. Their activation should thus directly hyperpolarize substantia gelatinosa neurons and produce an inhibitory effect on the sensory transmission. However, application of 5-HT<sub>1A</sub> and 5-HT<sub>1B</sub> receptor agonist was also shown to increase responses of WDR neurons to peripheral stimulation (Zhang *et al.*, 2001a). This may be mediated by the presence of 5-HT<sub>1</sub> receptors on GABAergic interneurons, which would consequently be inhibited upon stimulation of the 5-HT<sub>1</sub> receptors (Millan *et al.*, 1996). 5-HT<sub>2</sub> receptors are positively coupled to phospholipase C, and thus exert excitatory influences on neuronal activity. The antinociceptive effects attributed to the 5-HT<sub>2A</sub> subtype (Courade *et al.*, 2001; Kjorsvik *et al.*, 2001; Radhakrishnan *et al.*, 2003; Sasaki *et al.*, 2003) would thus also have to be caused by the activation of inhibitory interneurons. Interestingly, 5-HT<sub>2A</sub> receptors are scarce in normal spinal cord but are up-regulated after inflammation, indicating a state-specific action of 5-HT on these receptors (Zhang *et al.*, 2001b).

The ionotropic 5-HT<sub>3</sub> receptor increases neuronal excitability, and has been found to mediate descending facilitation through serotonergic pathways (Rahman *et al.*, 2004; Suzuki *et al.*, 2004a). A study with mice deficient of the 5-HT<sub>3</sub> receptor came to the conclusion that this receptor was proalgesic at peripheral and spinal sites (Zeititz *et al.*, 2002). If 5-HT acts on a presynaptic spinal 5-HT<sub>3</sub> receptor, excitatory neurotransmitter release is increased. Concordantly, ondansetron, a 5-HT<sub>3</sub> antagonist, reduces pain behavior upon mechanical stimuli after nerve injury (Suzuki *et al.*, 2004a) and mechanical allodynia after spinal cord injury in rats (Oatway *et al.*, 2004). Furthermore, from experiments ablating NK1-positive neurons in the spinal cord it was postulated that NK1 positive lamina I projection neurons form the origin of a spino-bulbo-spinal loop, which controls spinal excitability through the activation of a descending serotonergic pathway (Suzuki and Dickenson, 2005; Suzuki *et al.*, 2005). On the other hand, there is an inhibitory action of spinal 5-HT through the release of GABA from inhibitory interneurons via 5-HT<sub>3</sub> receptors (Alhaider *et al.*, 1991). This is in accordance with the recent finding of a colocalization of 5-HT<sub>3</sub> receptors and GABA in the spinal cord dorsal horn (Huang *et al.*, 2008).

In the formalin model, 5-HT<sub>1B</sub>, 5-HT<sub>2C</sub>, 5-HT<sub>3</sub> and 5-HT<sub>4</sub> receptors have been implied in 5-HT mediated

analgesia (Jeong *et al.*, 2004). Kayser and colleagues investigated mice deficient in 5-HT<sub>1A</sub>, 5-HT<sub>1B</sub>, 5-HT<sub>2A</sub> and 5-HT<sub>3A</sub> in parallel with a panel of behavioral tests in the attempt to dissect out spinal, supraspinal and peripheral effects of 5-HT (Kayser *et al.*, 2007). 5-HT<sub>1A</sub> knockout mice differed from wild types by higher thermal sensitivity, and 5-HT<sub>1B</sub> knockout mice by higher thermal and formalin sensitivity. Both 5-HT<sub>2A</sub> and 5-HT<sub>3A</sub> knockout mice differed from wild types by a dramatic decrease in the formalin-induced nociceptive responses for phase 2. The authors concluded that 5-HT<sub>1B</sub> and to a lesser degree 5-HT<sub>1A</sub> receptors were responsible for endogenous inhibitory control of nociception by 5-HT, whereas 5-HT<sub>2A</sub> and 5-HT<sub>3</sub> receptors had a role in peripheral hyperalgesia.

5-HT released from the brainstem nuclei was first shown to have an analgesic action at spinal sites as part of the system of descending inhibition (Yaksh and Wilson, 1979). Stimulation in the PAG and NRM releases 5-HT in the dorsal horn and excites 5-HT<sub>2</sub> or 5-HT<sub>3</sub> receptors on inhibitory interneurons, which in turn inhibit dorsal horn neurons (Peng *et al.*, 1996). However, more recently data have accumulated, first questioning a major role of 5-HT in descending analgesia, then showing even a facilitatory effect of 5-HT on nociceptive transmission. Depending upon the stimulus parameters, brainstem stimulation can cause hyperalgesia, and there is evidence that this is also mediated by descending serotonergic pathways (Zhuo and Gebhart, 1991). One reason underlying this two-fold action of 5-HT may lie in the fact that the result of RVM stimulation depends on whether 'on cells' or 'off cells' are activated (Fields *et al.*, 1983). Accordingly, 5-HT receptor antagonists can reduce both the pain-facilitating and pain-inhibiting effects of stimulation of the RVM. Some of the serotonergic RVM neurons appear to be 'on cells' themselves, because they are labeled with the neural activity marker c-fos after noxious stimulation of a rat hindpaw (Suzuki *et al.*, 2002). However, others dispute that either 'on' or 'off' cells are serotonergic (Fields, 2004), and regard the RVM-serotonergic system as a parallel but distinct pain-controlling system that may be under opioidergic control (Fields, 2004). In analogy to the opioidergic system of 'on' and 'off' cells, 5-HT is supposed to act in an activity-dependent mode, thus eliciting different behaviors at different times.

A very telling model to study the role of central 5-HT is provided by conditional knockout mice selectively deficient of 5-HT in central neurons. This was achieved by generating mice deficient of a transcription factor required for the differentiation of postmitotic 5-HT neurons (Ding *et al.*, 2003). These Lmx1b<sup>f/t/p</sup> mice are less sensitive to mechanical stimuli, but showed normal thermal and visceral pain responses. The mice had increased mechanical hypersensitivity after capsaicin injection, and increased

pain behavior in the second phase of the formalin test (Zhao *et al.*, 2007a). The phenotype could be rescued by intrathecal injection of 5-HT. Antidepressants (fluoxetine, amitriptyline and duloxetine) had no effect on thermal pain in the *Lmx1b<sup>fl/p</sup>* mice. Flinching in the second phase of the formalin test was attenuated by duloxetine, but not by the selective 5-HT reuptake inhibitor fluoxetine. Together, the findings from this study support the view that 5-HT is of fundamental importance for the analgesic effect of antidepressants (Zhao *et al.*, 2007a). *Lmx1b<sup>fl/p</sup>* mice were also helpful in delineating the role of 5-HT in the action of opioids (Zhao *et al.*, 2007b).

5-HT is also involved in other complex regulatory circuits. For example, rapid eye movement (REM) sleep deprivation facilitates pain sensitivity. REM sleep deprivation in rats produced marked hypersensitivity to tactile stimuli via endogenous 5-HT acting on 5-HT<sub>1A</sub> and 5-HT<sub>2C</sub> receptors (Wei *et al.*, 2008). Thus, sustained activation of these receptors contributes to maintenance of cutaneous hypersensitivity in sleep-deprived animals.

#### *5-HT receptor agonism and antagonism for pain relief*

As mentioned above, the 5-HT<sub>1B/D</sub> agonist sumatriptan, 5-HT<sub>2A</sub> antagonists, and the 5-HT<sub>3</sub> receptor antagonist tropisetron have been shown to reduce pain behavior in certain animal models. Furthermore, a state-dependent analgesic effect of the 5-HT<sub>1A</sub> agonist F 13640 was found in rat models of acute and chronic nociceptive and neuropathic pain (Deseure *et al.*, 2007).

In contrast, the spinal excitatory action of 5-HT on 5-HT<sub>3</sub> receptors was shown to be necessary for the analgesic effect of gabapentin (Suzuki *et al.*, 2005). This finding may be of clinical relevance, since not all patients with neuropathic pain respond favorably to gabapentin. The 5HT<sub>3</sub>-mediated spino-bulbo spinal loop, influenced by the affective state of the patient, might be part of determining this response (Suzuki *et al.*, 2005).

The greatly reduced analgesic effect of antidepressants in mice lacking central serotonergic neurons (Zhao *et al.*, 2007a) also indicates a dependence of their effect on 5-HT, even in dual antidepressants like duloxetine. By studying the expression of norepinephrine transporter, the authors could largely exclude a secondary effect through the norepinephrine system.

#### *5-HT and the action of opioids*

Various experimental studies have shown an interaction of the serotonergic system and morphine analgesia. Serotonergic pathways are thought to be functionally distinct from but to interact with the opioid-mediated pain-modulatory circuit (Fields, 2004). 5-HT in the NRM may be necessary for the action of morphine (Sounvoravong

*et al.*, 2004). Morphine has direct actions at the 5-HT<sub>3</sub> receptor, suppressing 5-HT-induced currents in neurons in a competitive way (Wittmann *et al.*, 2006). Using the selective receptor antagonist SB-269970, the analgesic effects of systemic morphine in mice were shown to be dependent on the 5-HT<sub>7</sub> receptor (Dogrul and Seyrek, 2006). Interactions between the serotonergic, GABAergic and opioidergic system have been shown (Nemmani and Mogil, 2003).

*Lmx1b<sup>fl/p</sup>* mice which lack central serotonergic neurons have no analgesia after administration of a kappa opioid receptor agonist and significantly reduced analgesic effects of  $\mu$ - and  $\delta$ -opioid receptor agonists at both spinal and supraspinal sites. In contrast, morphine tolerance and morphine reward behavior developed normally in these mice (Zhao *et al.*, 2007b). Thus, the central serotonergic system is a necessary component of the supraspinal pain modulatory circuitry mediating opioid analgesia. In contrast, morphine tolerance and morphine reward appear to be independent of the central serotonergic system. Interestingly, tramadol, a drug successfully used in pain management, acts through a combination of  $\mu$ -opioid receptor and 5-HT<sub>1A</sub> receptors (Berrocso *et al.*, 2007).

#### **Data from human studies**

Plasma 5-HT levels were found to be increased in several painful conditions (Table 1) – for example, in the complex regional pain syndrome (CRPS) (Wesseldijk *et al.*, 2008). Also, interstitial concentrations of 5-HT in the trapezius muscle were increased in patients with whiplash-associated disorders (Gerdle *et al.*, 2008) and with work-associated trapezius muscle pain (Larsson *et al.*, 2008). Both findings point to a role of 5-HT as a peripheral pain mediator, among others, in these conditions. In an earlier study, blood 5-HT levels correlated negatively with pain detection thresholds but not with pain tolerance, also indicating a peripheral nociceptive effect of 5-HT (Pickering *et al.*, 2003). As detailed above in the section on 5-HT agonists and antagonists, 5-HT injection in human volunteers induces sensitization to other mediators (Babenko *et al.*, 2000), or pain and itching (Lischetzki *et al.*, 2001; Schmelz *et al.*, 2003), or hyperalgesia (Ernberg *et al.*, 2000, 2006). An indirect indication for the role of 5-HT in experimental pain comes from the study on the GTP cyclohydrolase haplotype (Tegeder *et al.*, 2006), the rate-limiting enzyme for tetrahydrobiopterin synthesis, a cofactor for serotonin production. Low tetrahydrobiopterin (and thus presumably low 5-HT synthesis) was associated with reduced experimental pain.

Genetic variants in 5-HT receptors or in the 5-HT transporter have been hypothesized to underlie the variability

**Table 1** List of painful disorders where a role of 5-HT has been suggested

Disorder	Finding	Reference
Migraine, between attacks	Lower plasma 5-HT, higher 5-HIAA	Ferrari <i>et al.</i> , 1989; Sicuteri <i>et al.</i> , 1961
Migraine, during attacks	Higher plasma 5-HT, lower 5-HIAA	Ferrari <i>et al.</i> , 1989
Medication overuse in migraine	Lower plasma 5-HT levels	Hering <i>et al.</i> , 1993
Migraine, between attacks	Increased availability of the 5-HTT in brainstem	Schuh-Hofer <i>et al.</i> , 2007
Migraine treatment	5-HT <sub>1B/D</sub> receptor agonists abort migraine attacks	Ferrari <i>et al.</i> , 2002
Migraine with aura	Higher frequency of the short allele of the 5-HTTLPR	Borroni <i>et al.</i> , 2005; Marziniak <i>et al.</i> , 2005
Medication overuse headache	Platelet 5-HT uptake increased	Ayzenberg <i>et al.</i> , 2008
Complex regional pain syndrome (CRPS)	Plasma 5-HT levels increased	Wesseldijk <i>et al.</i> , 2008
Whiplash associated pain	Interstitial 5-HT concentrations in the trapezius muscle increased	Gerdle <i>et al.</i> , 2008
Work-associated trapezius muscle pain	Interstitial 5-HT concentrations in the trapezius muscle increased	Larsson <i>et al.</i> , 2008
Fibromyalgia syndrome	Reduced 5-HT levels in CSF	Houvenagel <i>et al.</i> , 1990; Russell <i>et al.</i> , 1992a
Fibromyalgia syndrome	Reduced serum 5-HT levels	Russell <i>et al.</i> , 1992b; Stratz <i>et al.</i> , 1993
Fibromyalgia syndrome	Higher frequency of the short allele of the 5-HTTLPR	Offenbaecher <i>et al.</i> , 1999; but see also Gürsoy <i>et al.</i> , 2002
Fibromyalgia syndrome	T102C polymorphism of the 5-HT <sub>2A</sub> -receptor	Bondy <i>et al.</i> , 1999; Gürsoy <i>et al.</i> , 2001

Abbreviations: 5-HIAA, 5-hydroxyindole-acetic acid; 5-HTT, 5-HT transporter; 5-HTTLPR, 5-HTT-gene linked polymorphic region; CSF, cerebrospinal fluid.

in pain sensations in normal and diseased states. Recently, the intensity of cold pressure pain was investigated in 11 volunteers who had undergone positron emission tomography (PET) examination to quantify their 5-HT<sub>1A</sub> binding potential. Cold pressure pain intensity inversely correlated with the 5-HT<sub>1A</sub> binding potential in multiple cortical and subcortical areas. Subjects with high availability of 5-HT<sub>1A</sub> receptors had low cold pressure pain intensity and a high capacity for central suppression of

pain by a Valsalva maneuver (Martikainen *et al.*, 2007). This led to the conclusion that brain 5-HT<sub>1A</sub> receptors influence pain thresholds and the capacity for analgesia in healthy subjects.

In a PET study using the 5-HT<sub>2A</sub> receptor antagonist [(18F)]altanserin for imaging, positive correlations were found between tonic pain ratings and binding in orbito-frontal, medial inferior frontal, primary sensory-motor and posterior cingulate cortices (Kupers *et al.*, 2009). The authors concluded that 5-HT<sub>2A</sub> receptor availability co-varies with responses to tonic pain, and that the correlation between 5-HT<sub>2A</sub> receptor availability in prefrontal cortex and tonic pain suggests a possible role of this brain region in the modulation or cognitive appreciation of pain.

### 5-HT in headache

The study of 5-HT in headache, in particular in migraine, has a long history (Sicuteri *et al.*, 1961). Lower plasma 5-HT and relatively higher levels of 5-hydroxyindole-acetic acid, a metabolite of serotonin degradation, were reported in patients with migraine between attacks (Sicuteri *et al.*, 1961; Ferrari *et al.*, 1989). In contrast, during an attack increases in plasma 5-HT concomitant with decreases in 5-HIAA levels have been found (Ferrari *et al.*, 1989; for review, see Hamel, 2007). This led to the hypothesis that a chronic 5-HT deficit may be at the biochemical basis of migraine, while intermittent increases in 5-HT are triggers for migraine attacks. The 5-HT inhibitor methysergide was the first potent drug for migraine prophylaxis (Koehler and Tfelt-Hansen, 2008).

5-HT binds to the 5-HT<sub>1B/D</sub> receptors with higher affinity than to 5-HT<sub>2A</sub> receptors. Binding of 5-HT to the 5-HT<sub>1B/D</sub> receptors, when present at low concentrations in the migraine-free period results in stabilization of the perivascular nociceptors. When released at higher concentrations, 5-HT will bind to the proalgesic 5-HT<sub>2A</sub> receptors and may thus trigger a migraine attack. This is another example of the dual action of 5-HT in the nociceptive system depending on concentration, receptor availability and receptor affinity. Medication overuse further leads to reduced 5-HT levels in the blood of migraine patients (Hering *et al.*, 1993). This in turn may lead to upregulation of 5-HT<sub>2</sub> receptors, which when stimulated can increase the occurrence of migraine attacks, possibly via NO (Srikiatkhachorn *et al.*, 2002). These changes are reversible after medication withdrawal (Smith, 2004).

In a single photon emission computed tomography (SPECT) study using a selective 5-HTT ligand, increased availability of 5-HTT was found in the brainstem interictally in migraine patients (Schuh-Hofer *et al.*, 2007). This

finding is compatible with decreased extracellular levels of 5-HT at the synaptic cleft and thus deregulation of the 5-HT system in the brainstem.

Physiological studies found that the amplitude of auditory- and visual-evoked potentials increased in migraineurs interictally, indicative of low 5-HT transmission. This was attributed to a deficit in cortical habituation (Coppola *et al.*, 2005). The triptans, 5-HT<sub>1B/1D</sub> receptor agonists, activate inhibitory presynaptic 5-HT<sub>1B/1D</sub> autoreceptors to decrease 5-HT synthesis. They increase the amplitude of auditory-evoked potentials in both normal subjects and migraine patients (Proietti-Cecchini *et al.*, 1997). Treatment with the  $\beta$ -blocker propranolol increases the rate of brain 5-HT synthesis, which may be the mechanism of action of  $\beta$ -blockers in migraine prophylaxis (Chugani *et al.*, 1999). There is some experimental evidence for a connection between 5-HT, cortical spreading depression (which is thought to underlie the migraine aura) and trigemino-vascular activation (which is thought to underlie the cephalalgia in migraine). Rats with low 5-HT had enhanced cortical spreading depression waves and an increased number of activated neurons in the trigeminal nucleus caudalis (Supornsilpchai *et al.*, 2006). Thus, chronically low brain 5-HT may facilitate trigeminal nociception through induction of cortical spreading depression, consistent with a deficit in the serotonergic descending pain inhibitory system (Panconesi, 2008).

The triptans, 5-HT<sub>1B/1D</sub> receptor agonists, are the most successful drugs for acute migraine attacks (Ferrari *et al.*, 2002). It is assumed that their action via the 5-HT<sub>1B/1D</sub> receptors inhibits excitation of the perivascular trigeminal fibers, and thus blocks the release of vasoactive peptides (substance P, calcitonin gene-related peptide/CGRP) in the dura mater (Potrebic *et al.*, 2003). Triptans may exert part of their actions on trigeminal nuclei, inhibiting the activity trigeminal fibers centrally (Edvinsson and Uddman, 2005). Serotonergic RVM neurons project to cerebral vessels (Bradley *et al.*, 2002), where they regulate microcirculation (Cohen *et al.*, 1996). When raphe nuclei are activated, they can increase cerebral blood flow (Goadsby, 2005). Triptans also bind to receptors on the dorsal raphe and periaqueductal gray (Bonaventure *et al.*, 1998), indicating that, if they penetrate the blood-brain barrier, they may also act at these nuclei.

Genetic factors within the serotonergic pathways have been investigated for their role in migraine susceptibility. Most studies investigating 5-HT receptors, the TPH gene or MAOA, MAOB polymorphisms were negative. The most convincing evidence so far for a genetic association between the serotonergic system and migraine has been obtained for the association of polymorphisms in 5-HTT, which controls 5-HT brain homeostasis.

We examined a functional deletion/insertion polymorphism in the transcriptional control region 1 kb upstream of the 5-HTT gene's transcription initiation site (5-HTT-linked polymorphic region, HTTLPR). *In vitro* and *in vivo* studies have demonstrated the functional relevance of this polymorphism with reduced transcriptional activity and low 5-HT reuptake activity determined by the short form of the allele (Lesch *et al.*, 1996). Patients with migraine with aura had a significantly higher frequency of the short allele of the 5-HTTLPR in comparison to a control population and to patients with migraine without aura (Marziniak *et al.*, 2005). These results were confirmed in an independent Italian population (Borroni *et al.*, 2005), while a Hungarian group found an association with migraine in general in women (Gonda *et al.*, 2007) and yet another group reported a link with increased frequency of migraine attacks (Kotani *et al.*, 2002). Interestingly, platelet 5-HT uptake is increased in patients with medication-overuse headache concomitantly with a transient increase in 5-HTT activity, and normalizes after withdrawal in parallel to the improvement of headache frequency (Ayzenberg *et al.*, 2008).

### **Fibromyalgia syndrome**

Fibromyalgia syndrome (FMS) is a complex of symptoms associated with chronic widespread pain and tenderness upon pressure on at least 11 of 18 predefined anatomical points (Wolfe *et al.*, 1990). Additional symptoms are fatigue, sleep disturbance, depression, and gastrointestinal symptoms such as diarrhea and constipation. An effect of systemic 5-HT<sub>3</sub> antagonists was occasionally reported (Spath *et al.*, 2004). Together with the constellation of symptoms, this led to the hypothesis that 5-HT might be involved in the pathophysiology of FMS. Two studies investigating 5-HT levels in CSF found a reduction in patients with FMS compared to controls (Russell *et al.*, 1992a) or to reference data from the general population (Houvenagel *et al.*, 1990). In serum, reduced levels of serotonin were found in three studies (Russell *et al.*, 1992b; Stratz *et al.*, 1993; Wolfe *et al.*, 1997). Others investigated whether antibodies against serotonin or serotonin receptors were present in patients with FMS (Klein *et al.*, 1992; Werle *et al.*, 2001), and found these in a higher percentage than in controls. It is unclear if these antibodies play a pathophysiological role in FMS.

Of two studies investigating an association of FMS with polymorphisms in the 5-HTT promoter region, one found a higher percentage of the S/S genotype; these patients had higher scores in tests for depression and psychosocial impairment (Offenbaeher *et al.*, 1999). In the other study, however, no association was found (Gürsoy, 2002). Of the

four studies that investigated serotonin receptors (Bondy *et al.*, 1999; Gürsoy *et al.*, 2001; Frank *et al.*, 2004; Tander *et al.*, 2008), two were positive, both of them for the T102C polymorphism of the 5-HT<sub>2A</sub>-receptor (Bondy *et al.*, 1999; Gürsoy *et al.*, 2001). A study investigating other 5-HT<sub>2A</sub> receptor gene polymorphisms (Tander *et al.*, 2008) and one studying variations in the 5-HT<sub>3A</sub> and 5-HT<sub>3B</sub> genes (Frank *et al.*, 2004) were negative.

5-HT<sub>3</sub> antagonists have been repeatedly studied in open trial in FMS. However, in contrast to chemotherapy-induced vomiting, where 5-HT<sub>3</sub> antagonists are extremely successful (Faerber *et al.*, 2007), in FMS only one randomized controlled trial has shown a moderate effect upon short-term treatment (Färber *et al.*, 2000).

In summary, a definite role of 5-HT in the pathogenesis of FMS is possible, but has not yet been proven.

### ***Implications for the treatment of chronic pain with antidepressants***

Metareviews indicate that combined serotonergic and noradrenergic reuptake inhibitors such as the tricyclic antidepressants (TCA) are efficient analgesics, in particular in neuropathic pain, while selective serotonin reuptake inhibitors (SSRIs) are less efficient (Saarto and Wiffen, 2005). Similarly, the effect of SSRIs in the prevention of migraine and tension-type headache is also poor (Moja *et al.*, 2005). Since relative selective noradrenalin reuptake inhibitors are also less effective in pain treatment, it has been suggested that a combined serotonergic and noradrenergic mechanism is needed. In view of the dual role of 5-HT in the pain-modulating system, it is not surprising that an increased availability of 5-HT at synapses may not in all instances lead to analgesia. Since the good pain control with TCA is set off by their side effects, combined serotonin–noradrenalin reuptake inhibitors (SNRIs) such as venlafaxine and duloxetine have been studied in clinical trials; these have fewer side effects and efficacy only slightly inferior to that of TCA (Sindrup *et al.*, 2005). In particular, in FMS, SNRIs appear to be effective in reducing pain levels (Clauw *et al.*, 2008; Üceyler *et al.*, 2008a, 2008b).

### **Conclusion**

There is no simple answer regarding the question of the role of 5-HT in pain and in pain control. It may be most easily solved in the periphery, where 5-HT, released into inflamed or injured tissues, contributes to peripheral sensitization of nerve fibers (Figure 1). In the trigemino-vascular system and in the CNS there are dual actions

of 5-HT, depending on receptor availability and affinity, ligand concentration, and the neural network involved. The situation is even more complicated concerning the algesic or analgesic action of 5-HT in descending pathways and in the spinal cord (Figure 2). The concept of state-dependent actions, as recently proposed for the opioid system (Fields, 2004), may have to be adapted to the serotonergic system as well. Analgesics aiming at the serotonergic system have to take all these points into account.

# The Impact of Stress on Serotonergic Neurotransmission

Astrid C.E. Linthorst\* and Johannes M.H.M. Reul

*Henry Wellcome Laboratories for Integrative Neuroscience and Endocrinology (HW-LINE), University of Bristol, Bristol, UK*

**Abstract:** Levels of stress perceived by people in our modern society seem to have risen considerably, a phenomenon which may be related to the increased incidence of stress-related mental health problems such as depression and anxiety disorders. Whereas the body is well equipped to deal with single, acute stressful challenges, regulatory systems may derail when stress is of a repeated or prolonged nature. Two of the systems that appear to be malfunctioning in psychiatric disease are the hypothalamic–pituitary–adrenocortical (HPA) axis (i.e., the stress hormone axis) and the serotonin (5-HT) system. This chapter will focus on the effects of stress on serotonergic neurotransmission. We will first discuss how stress affects the activity of the serotonergic cell bodies in the rostral (midbrain/pontine) raphe nuclei (the dorsal and median raphe nucleus), followed by an overview of the effects of stress on 5-HT synthesis. The dorsal and median raphe nuclei project to major limbic forebrain structures involved in the coordination of the stress response, such as the frontal cortex, hippocampus, amygdala and hypothalamus. Therefore, we will subsequently highlight the effects of stress on the extracellular levels of 5-HT in these structures as assessed by *in vivo* microdialysis. Next, the (aberrant) functioning of serotonergic neurotransmission in animal models with changes in HPA axis regulation will be discussed, followed by an excursion into the beneficial effects of moderate exercise on stress coping mechanisms.

The reviewed data clearly demonstrate that the neurotransmitter 5-HT is not only highly responsive to acute stress; its responses are also intricately coordinated in a stressor-dependent and brain region-specific manner. This notion holds true for the regulation of the firing rate of serotonergic neurons, the activity and expression of tryptophan hydroxylase (the rate-limiting enzyme in the synthesis of 5-HT) and the extracellular levels of 5-HT in terminal regions. Furthermore, these data show that the 5-HT system can become compromised during situations of aberrant functioning of the HPA axis – for example, due to changes in the corticotropin-releasing factor system or in corticosteroid receptor function. Most data presented here are obtained during and following acute stressful challenges. This information is of great relevance for our understanding of the relationship between stress and 5-HT. However, there is unfortunately only very limited information available on the effects of repeated and chronic stress. With respect to mental health disease (and animal welfare), it will therefore be essential to make the next step and increase our knowledge on how prolonged stress may perturb serotonergic neurotransmission. Finally, as stress will not suddenly ‘disappear’ from our society, and the costs of stress-related disease are burdening the health systems of many countries, it is important to study the mechanisms underlying adequate coping with stress and stress resilience, and to find ways to improve and support such mechanisms – for example, by exercise.

**Abbreviations:** 5-HT, serotonin (5-hydroxytryptamine); 5-HIAA, 5-hydroxyindoleacetic acid; CRF, corticotropin-releasing factor; CRF1, corticotropin-releasing factor receptor type 1; CRF2, corticotropin-releasing factor receptor type 2; DRN, dorsal raphe nucleus; GR, glucocorticoid receptor; HPA, hypothalamic-pituitary-adrenocortical; MRN, median raphe nucleus; SSRI, selective serotonin reuptake inhibitor; TPH, tryptophan hydroxylase.

## Introduction

In our modern society stress seems to be an omnipresent phenomenon. Many people complain about having to deal with stressful situations either at work or in the family, or

are suffering from stress for an extended period of time. Even children will sometimes say that they feel ‘stressed’. A detailed discussion of the reasons for the rise in the perceived levels of stress nowadays is beyond the scope of this chapter, but the increased speed of life in general and the concurrent floods of information to be processed may play a prominent role. Naturally, uncertainties regarding the economy, together with an unstable job and housing market, present major causes of stress in many people’s lives.

When combined with a sedentary lifestyle and unhealthy eating habits, stress coping mechanisms may fail and the damaging effects of chronic stress on physical and mental health will become evident.

In principal, the human body is well-equipped to deal with single stressful events, but when stress becomes chronic (for example, during care of ill or older relatives, prolonged financial problems, etc.) it may precipitate disease. It is now well accepted that stress – or maybe, more accurately phrased, mal-coping with stress – is involved in the etiology of certain psychiatric diseases such as major depression and anxiety disorders. In depressed patients, major aberrations have been found in the regulation of the stress hormone system, the hypothalamic–pituitary–adrenocortical (HPA) axis, under both baseline and challenged conditions (De Kloet *et al.*, 2005). Thus, major depression is, for instance, associated with a flattened circadian rhythm of cortisol and with impaired suppression in the dexamethasone suppression test – a neuroendocrine challenge test to assess negative feedback efficacy within the HPA axis via the glucocorticoid receptor (GR). Analyses of CSF samples and *post-mortem* tissues of depressed patients have provided evidence for alterations at the level of the corticotropin-releasing factor (CRF) system, which is one of the key regulators of the activity of the HPA axis and also plays an important role in stress-related behaviors such as fear and emotion (Nemeroff *et al.*, 1984, 1988; Raadsheer *et al.*, 1994, 1995; Arborelius *et al.*, 1999). Furthermore, modern molecular techniques have shown that alterations at the level of the genome – in genes involved in HPA axis regulation – may render individuals more susceptible to the development of a mood or anxiety disorder (Binder *et al.*, 2004a; Derijk *et al.*, 2006; van Rossum *et al.*, 2006).

As described in detail elsewhere in this volume, the neurotransmitter serotonin (5-HT) plays an important role in the etiology of mood and anxiety disorders (see also Maes and Meltzer, 1995; Mann, 1998; Ressler and Nemeroff, 2000). Many of the available pharmacological treatments for these illnesses involve manipulating the 5-HT system in one way or another (e.g., selective serotonin reuptake inhibitors (SSRIs) and buspirone, a 5-HT<sub>1A</sub> receptor partial agonist). Importantly, it has been found that alterations in genes of the 5-HT system, such as polymorphism in the promoter region of the 5-HT transporter gene, can moderate the impact of stressful life events on depression (Caspi *et al.*, 2003). Thus, given the prominent role of both the HPA axis and 5-HT in stress-related psychiatric disease, the question arises as to whether and how stress influences the 5-HT system and, furthermore, whether stress exerts its effects on 5-HT via components of the stress hormone axis (i.e., involving glucocorticoids and neuropeptides of the CRF family). We endeavor to answer these questions in this chapter as follows. In the next section, we will first review evidence demonstrating

the responsiveness of the rostral serotonergic raphe nuclei to stressful challenges; this in terms of c-Fos expression in 5-HT neurons and changes in the firing rate of these neurons. Next, the effects of stress on the synthesis of 5-HT and on the expression of the rate-limiting enzyme tryptophan hydroxylase (TPH) will be discussed. The subsequent section will be devoted to the effects of stress on extracellular levels of 5-HT – as assessed by *in vivo* microdialysis – in regions of the forebrain which are essential for the coordination of the various components of the stress response. Finally, the consequences of manipulating the HPA axis and the CRF system for serotonergic neurotransmission will be considered. The data discussed in this chapter underscore the concept that stress impacts on the 5-HT system in a stressor- and brain-region-dependent manner, involving, under certain circumstances, glucocorticoid hormones and CRF and related neuropeptides. Given that current pharmacological therapies for the treatment of stress-related mental health diseases are still unsatisfactory – especially because of profound side effects, delay in clinical efficacy and a significant proportion of treatment-resistant patients – the intricate interaction between stress and 5-HT should be taken as a stimulant to further investigate the role of and identify new drug targets in these systems in depression and anxiety disorders. As outlined towards the end of the chapter, it will furthermore be of great importance to study the impact of moderate exercise on the 5-HT system in more detail so as to increase our understanding of why exercise is beneficial in the treatment of mental health diseases, and why, putatively, it could be used for the prevention of the development of such illnesses.

### Effects of stress on the raphe nuclei: c-Fos expression and neuronal firing

In this chapter we will focus on the rostral 5-HT system, with cell bodies located in the dorsal raphe nucleus (DRN), the caudal linear nucleus and the median raphe nucleus (MRN), and providing a dense innervation to the whole forebrain (for neuroanatomical details, see Chapter 1.3 of this volume).

The immediate early gene c-Fos is often used as a marker to identify neurons that are activated by various manipulations (Kovacs, 1998). Using this strategy, it has become increasingly clear that stress indeed activates neurons within the DRN and MRN. Increased expression of c-Fos mRNA has been demonstrated after exposure of animals to different psychological stress paradigms, such as inescapable tail-shock, elevated plus maze (a behavioral test for the assessment of anxiety levels in rodents), social defeat stress, immobilization stress, restraint and

fear conditioning (Pezzone *et al.*, 1993; Silveira *et al.*, 1993; Watanabe *et al.*, 1994; Cullinan *et al.*, 1995; Beck and Fibiger, 1995; Martinez *et al.*, 1998; Grahm *et al.*, 1999; Ishida *et al.*, 2002; Rioja *et al.*, 2006; Lehner *et al.*, 2008). Forcing rats to swim – a stressor with not only psychological but also physical aspects (see below) – also induces c-Fos mRNA expression in both the DRN and MRN (Cullinan *et al.*, 1995). In contrast, activation of the immune system, which is regarded as a ‘systemic’ stressor representing an immediate physiological threat to the organism, seems to have no clear effect on c-Fos expression in the DRN and MRN in the rat (Ericsson *et al.*, 1994; Elmquist *et al.*, 1996; Laflamme *et al.*, 1999). However, in a recent study Hollis and colleagues demonstrated Fos-immunoreactivity in a specific subset of serotonergic neurons in the DRN (i.e., within the interfascicular and ventrolateral division of this raphe nucleus) after administration of bacterial endotoxin to mice (Hollis *et al.*, 2006). Interestingly, a topographically specific activation of neurons in the DRN has also been described after forced swim stress. Fifteen minutes of forced swimming in water at 25°C results in Fos-immunoreactivity in the dorsolateral DRN of rats (Roche *et al.*, 2003). Most of these Fos-positive neurons are, however, not 5-HT neurons but GABAergic interneurons, leading to the hypothesis that stress may regulate the neuronal activity of raphe 5-HT neurons (also) via its actions on the inhibitory neurotransmitter GABA within this nucleus. Given the observation that these Fos-positive neurons are enveloped by CRF fibers and contain CRF receptors (Roche *et al.*, 2003), it is of interest to note that intracerebroventricular administration of the CRF receptor type 1 (CRF1) ligands, CRF and urocortin 1, also causes a pronounced increase in Fos-immunoreactivity in the DRN (together with a moderate increase in the MRN) (Bittencourt and Sawchenko, 2000). In contrast, the CRF receptor type 2 (CRF2) ligand urocortin 2 has been found either to have no effect (Reyes *et al.*, 2001) or to increase the number of c-Fos-positive neurons mainly in the caudal regions of the DRN (Staub *et al.*, 2005). Administration of urocortin 2 directly into the caudal DRN results in an increased number of dual-labeled c-Fos/5-HT neurons in the caudal, middle and rostral DRN (Amat *et al.*, 2004). Interestingly, a recent study shows that in the caudal part of the DRN, levels of c-Fos expression correlate with the level of CRF-induced enhancement of the startle response in rats (Meloni *et al.*, 2008).

The above-described studies clearly show that stress (and members of the CRF neuropeptide family) results in a distinct and topographically specific neuronal activation of serotonergic (and other) neurons in the raphe nuclei. However, does this neuronal activation lead to changes in neuronal firing of 5-HT cell bodies in these

nuclei? Unfortunately, data from studies aiming to answer this important question are so far inconclusive. Studies by Barry Jacobs and colleagues have shown, using an *in vivo* electrophysiology approach, that in the cat the firing pattern of 5-HT cell bodies remains unchanged (as compared to the firing rate during active waking) during various forms of stress, such as noise stress, pain, and thermoregulatory and glucoregulatory challenges (for references, see Jacobs and Azmitia, 1992). Also, predator exposure, a challenge which increases extracellular 5-HT levels in higher brain structures in rodents, was found to be without effect in the DRN of the cat (Wilkinson and Jacobs, 1988). In contrast, using a brain slice approach, Laaris and colleagues showed that a longer period of stress (30-minute restraint followed by 24-hour isolation or 16-hour exposure to novel uncontrolled environmental conditions), but not acute restraint stress, results in a decreased 5-HT<sub>1A</sub> receptor-mediated inhibition of 5-HT cell firing rate in rats, which is dependent on corticosterone (Laaris *et al.*, 1997, 1999). Interestingly, early maternal separation (6 hours, 10 occasions, between postnatal days 5 and 20) has been found, *in vitro*, to decrease the sensitivity of DRN 5-HT neurons for  $\alpha$ 1-mediated excitation, but was without significant effect on the sensitivity of 5-HT<sub>1A</sub> receptors. Furthermore, this manipulation did not change the proportion of classical and burst-firing 5-HT neurons, although the range of firing rates seems to be increased in the early-life stressed group (Gartside *et al.*, 2003). Subsequent work by the same group elegantly demonstrated that the balance between  $\alpha$ 1-mediated excitation and 5-HT<sub>1A</sub>-mediated inhibition of the firing rate of DRN neurons is dependent on the level of corticosterone (Judge *et al.*, 2004). Thus, ADX rats implanted with a 2% corticosterone pellet show an enhanced  $\alpha$ 1-mediated excitation and a lower 5-HT<sub>1A</sub>-mediated inhibition of DRN firing as compared to animals with a 70% corticosterone pellet (Judge *et al.*, 2004). By contrast, using an *in vivo* electrophysiology approach, it was found that prolonged (180-minute, postnatal days 2–14) maternal deprivation results in an increased 5-HT<sub>1A</sub> autoreceptor-induced inhibition of raphe neuronal firing (Arborelius *et al.*, 2004). Studies on the effects of CRF on the firing rate of 5-HT neurons in the raphe nuclei have also provided evidence for a topographically specific influence. Thus, low doses of CRF were found to decrease the *in vivo* firing rate of 5-HT neurons in the rostral and medial parts of the DRN. Higher doses were without effect (Price *et al.*, 1998; Kirby *et al.*, 2000), whereas CRF increases the *in vitro* firing rate of a selective population of 5-HT neurons in the ventral and interfascicular region of the caudal DRN (Lowry *et al.*, 2000).

From the above, the picture is emerging that stress impacts on the activity of 5-HT neurons in the raphe

nuclei, but that it probably does so in a stressor- and topographically-specific way. Clearly more research is needed, implementing other stressful (acute and chronic) challenges and the effects of stress on non-classical (i.e., burst-firing) 5-HT neurons. Also, the role of glucocorticoid hormones needs to be further elucidated.

### Effect of stress on the synthesis of 5-HT

5-HT is synthesized from L-tryptophan, an essential amino acid which needs to be taken up via the diet and is transported into the brain via an L-type neutral amino acid transporter in the blood-brain barrier. The rate-limiting step in the synthesis of 5-HT is the conversion of L-tryptophan into 5-hydroxytryptophan (5-HTP), a step which is catalyzed by the enzyme tryptophan hydroxylase (TPH). TPH is present in enterochromaffin cells, myenteric neurons of the gut, the pineal gland, and the brain raphe nuclei. Next, 5-HTP is converted into 5-HT via decarboxylation by the enzyme aromatic L-amino acid decarboxylase (AADC). There is some evidence that, under certain circumstances, the availability of L-tryptophan to the brain can affect the level of synthesis of 5-HT (Fernstrom and Wurtman, 1971; Knott and Curzon, 1972; Boadle-Biber, 1993).

TPH is activated when stores of 5-HT need to be refilled, as evidenced by the rise in the synthesis of 5-HT from L-tryptophan during electrical stimulation of serotonergic cell bodies (Shields and Eccleston, 1972; Herr *et al.*, 1975; Boadle-Biber *et al.*, 1986). As discussed above, stress has distinct effects on neuronal activation and, putatively, consequently on the firing rate of 5-HT neurons in the raphe nuclei, leading to the obvious question of whether stress also influences TPH activity and expression. After the initial study of Azmitia and McEwen describing that prolonged cold and electric foot-shock stress increased TPH activity in the midbrain and forebrain of rats (Azmitia and McEwen, 1974), Margaret Boadle-Biber and colleagues have performed a large series of studies characterizing the effects of loud sound stress on 5-HT synthesis using an *ex vivo* TPH activity assay in rats. Applying this assay, it was found that one session of randomly presented sound stress causes a short-lasting activation of TPH in the cortex. This increase in TPH activity is persistent even 24 hours later when rats are exposed to repeated sound stress sessions (Boadle-Biber *et al.*, 1989). Importantly, as pointed out above, the enhanced TPH activity is related to increases in neuronal firing rate, as no effects were found when 5-HT neurons were silenced by pretreatment of the animals with the 5-HT<sub>1A</sub> receptor agonist gepirone (Corley *et al.*, 1992). The effects of stress seem to be dependent on

the availability of glucocorticoids, as adrenalectomy has been found to block the rise in TPH activity caused by sound stress (Singh *et al.*, 1990). The CRF system may also play a role in the regulation of TPH activity. Intracerebroventricular administration of CRF increases TPH activity, an effect in which glucocorticoid receptors play a permissive role (Singh *et al.*, 1992).

From the above studies, it has become clear that stress indeed impacts on the activity of TPH. However, the next question that arises is whether stress affects 5-HT synthesis in a neuroanatomically specific manner. Using an assay measuring the accumulation of 5-HTP after inhibition of AADC by m-hydroxybenzylamine, it was found that sound stress, forced swimming and tail-shock increased TPH activity in the MRN only, and were without effect in the DRN (Dilts and Boadle-Biber, 1995; Corley *et al.*, 2002). Furthermore, whereas CRF was found to increase TPH activity in the MRN (Singh *et al.*, 1992), this neuropeptide had no effect in the mediobasal hypothalamus (Van Loon *et al.*, 1982). A neuroanatomically specific effect of stress is further underscored by studies utilizing immobilization stress. Immobilization stress had no effect on TPH activity in the hypothalamus, hippocampus, amygdala and DRN after five sessions (Palkovits *et al.*, 1976), although it seemed to increase TPH activity in the locus coeruleus and to decrease activity in the suprachiasmatic nucleus after seven sessions (Culman *et al.*, 1984). Furthermore, using an *in vivo* microdialysis approach to measure the accumulation of 5-HTP, it was found that 1-hour immobilization results in increased 5-HT synthesis in the nucleus accumbens and the medial prefrontal cortex of the rat (Nakahara and Nakamura, 1999).

So far, we have reviewed the literature regarding the effects of stress on the activity of the TPH enzyme. However, much recent research has focused on the expression of TPH mRNA and on the levels of the TPH protein. In 2003, Walther and colleagues, in a seminal study published in *Science*, described for the first time the existence of a second TPH gene, *Tph2* (Walther *et al.*, 2003). The previously known gene is now called *Tph1*. Importantly, they demonstrated that *Tph2* is expressed exclusively in the brain (Walther *et al.*, 2003), and it was subsequently found that TPH2 controls the synthesis of 5-HT in the brain (Zhang *et al.*, 2004). The highest expression of TPH2 mRNA is found in the ventromedial DRN and MRN at the midrostral level (Clark *et al.*, 2006). Interestingly, TPH2 mRNA levels follow a circadian rhythm which is under the control of the suprachiasmatic nucleus (SCN) and is mediated by the circadian rhythm of corticosterone (Malek *et al.*, 2007). In contrast to TPH2, TPH1 mRNA is abundantly expressed in the pineal gland and the periphery. Although some studies have described

the absence of *Tph1* in the raphe nuclei (Walther *et al.*, 2003; Cote *et al.*, 2003), the picture is now emerging that low levels of TPH1 mRNA are expressed in the brain serotonergic cell bodies (Patel *et al.*, 2004; Abumaria *et al.*, 2008) in rodents. In *post-mortem* human brain, low levels of TPH1 mRNA are found in the raphe nuclei but more substantial levels have been observed in several forebrain regions (e.g., the hypothalamus and amygdala) (Zill *et al.*, 2007). Furthermore, TPH1 may play a role in the late stage of development, as peak levels of TPH1 mRNA at P21 have been described recently (Nakamura *et al.*, 2006). The effects of stress on the expression of the two *Tph* genes have not been fully clarified yet. Although TPH2 seems to be the most important enzyme form for 5-HT synthesis in the brain, no effects of 1-week daily restraint stress on TPH2 mRNA levels were found (Abumaria *et al.*, 2008). Also, chronic social stress was found to have no effect on the expression of TPH2 mRNA (Abumaria *et al.*, 2006). Furthermore, stress during early gestation seems to only cause marginal (trend to significance) effects on TPH2 mRNA in the DRN of male offspring (Mueller and Bale, 2008), whereas chronic administration of ovine CRF or urocortin 2 had no effect on the absolute expression of TPH2 mRNA in the DRN (although changes in the relative expression between the midrostral ventromedial and core dorsomedial DRN were observed) (Clark *et al.*, 2007). Recently it has been described that daily subcutaneous administration of the glucocorticoid receptor agonist dexamethasone (0.3–3 mg/kg subcutaneously for 4 days) decreased TPH2 protein levels in the raphe nuclei of mice, but, given the poor penetration of dexamethasone into the brain, the underlying mechanism of this observation needs to be further elucidated (Clark *et al.*, 2008). With respect to the marginal effects of stress on TPH2 described so far, it is interesting that, despite its low levels of expression in the brain, TPH1 is more clearly affected by stress. Thus, repeated immobilization or restraint stress has been found to substantially (by 2- to 10-fold) increase TPH1 mRNA levels in the DRN and MRN (Chamas *et al.*, 1999, 2004; Abumaria *et al.*, 2008). However, the effect of repeated immobilization stress on TPH1 mRNA expression seems to be independent of circulating glucocorticoids, as similar effects of the stressor were observed in adrenalectomized rats (Chamas *et al.*, 2004). The above-described findings clearly demonstrate the need for further research into the effects of stress on the two forms of TPH (at the gene and protein level), taking into account the possible stressor dependency and neuroanatomical specificity of such effects. Such studies will be of great importance not only for our basic understanding of the regulation of serotonergic neurotransmission, but also, given the changes observed in *Tph2* expression in suicide victims

(Bach-Mizrachi *et al.*, 2008) and the putative relationship between *Tph1* and *Tph2* gene variants and major depression (Zill *et al.*, 2004; Gizatullin *et al.*, 2006; Galfalvy *et al.*, 2008, but also see Gizatullin *et al.*, 2008), for further clarifying the role of 5-HT in stress-related psychiatric illnesses.

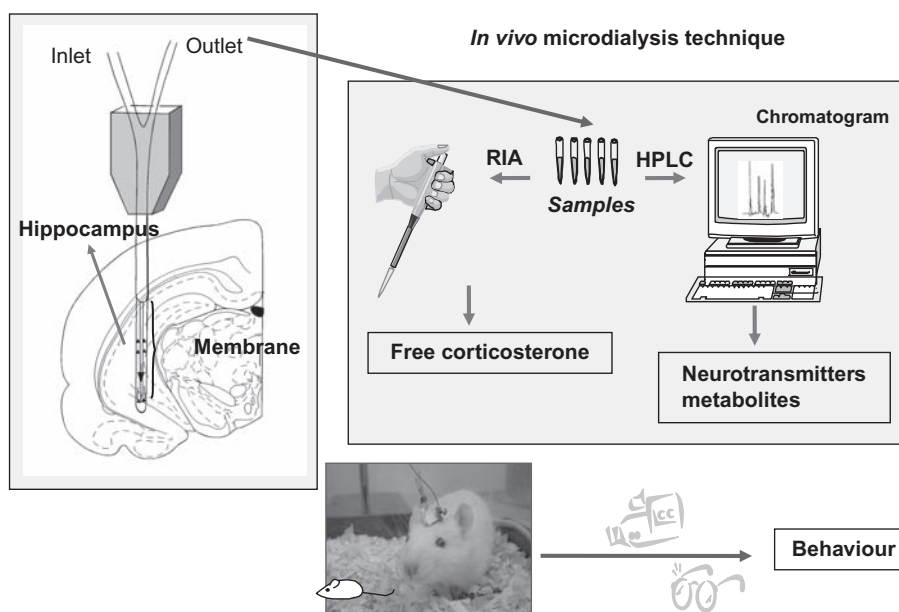

### Effects of stress on the extracellular levels of 5-HT and 5-hydroxyindoleacetic acid

During the past 25 years, *in vivo* microdialysis has become the method of choice to study extracellular levels of neurotransmitters in the brain. Microdialysis is predominantly used in neuropharmacology to evaluate the effects of (newly developed) drugs on neurotransmitter systems, and to elucidate their mechanisms of action. However, microdialysis is increasingly becoming an important tool to study the role of neurotransmitter systems in physiology and behavior. As we have recently discussed (Linthorst and Reul, 2008), several refinements in the performance of the technique, including the use of gas anesthesia, guide cannulas and special freely-moving animal systems, together with improved analytical methods, have made microdialysis extremely suitable for the study of various aspects of the stress response in rats and (mutant) mice (Figure 1). Below we will discuss the effects of stress on the extracellular levels of 5-HT and its metabolite 5-hydroxyindoleacetic acid (5-HIAA) in (1) three higher brain regions important in the behavioral and psychological aspects of the stress responses (i.e., the hippocampus, the frontal cortex and the amygdala) and (2) the hypothalamus and pre-optic area, because of their key role in the regulation of the endocrine and autonomic responses to stress.

#### Hippocampus, prefrontal cortex and amygdala

During recent years it has become clear that stress affects hippocampal levels of 5-HT and its metabolite 5-HIAA in a stressor-dependent way. Submitting rodents to predator stress, an ethologically highly relevant psychological stressor, has been found to increase extracellular levels of 5-HT and 5-HIAA in the hippocampus of rats and mice (Rueter and Jacobs, 1996; Linthorst *et al.*, 2000). In a recent study, we used a rapid sampling design (5 minutes during and immediately after the stressful challenge) to study the effects of exposure to a rat on the serotonergic neurotransmission in the hippocampus of male C57BL/6N mice (Beekman *et al.*, 2005). For this stressor, a male Wistar rat was introduced into the home cage of

**Figure 1** Schematic overview of the microdialysis technique as applied in our laboratories. A microdialysis probe is inserted through a guide cannula (not depicted, implanted 7–10 days earlier; the dialysis probe depicted is the CMA12 of CMA Microdialysis/AB, Stockholm, Sweden) exposing the dialysis membrane to the brain tissue of interest (shown here is the hippocampus). The microdialysis probe is perfused with Ringer solution via a microinfusion pump (not depicted). Drugs can be delivered to the target tissue by inclusion in the perfusion fluid (so-called retrodialysis or reverse dialysis). Animals are connected to a swivel system and counterbalance arm via a little peg anchored to the dental cement on their skull (see picture) giving them the opportunity to move freely in all directions. Samples are collected using automated microsamplers, and are subsequently used to measure various molecules in the dialysates – e.g., neurotransmitters and their metabolites – by high-pressure liquid chromatography (HPLC) with electrochemical detection or free corticosterone levels via radioimmunoassay (RIA). Behavior of the rats or mice is continuously scored during the microdialysis experiments by visual observation or is subsequently analyzed from videotape. Experiments are performed under baseline conditions, and during and following stressful challenges or behavioral testing. Note that this method allows the simultaneous collection of information on the status and responsivity of various neurotransmitter systems in the brain, on the activity of the HPA axis and on behavior, providing strong, integrative data and representing a clear example of refinement and reduction (Russell and Burch, 1959) in animal research. the mouse but remained separated from the mouse by a Plexiglas wall with small holes. Even during the first 5 minutes of the total 30 minutes of rat exposure, 5-HT levels increased rapidly, reaching maximum levels of about 300 percent of baseline. 5-HT remained elevated during the next 10 minutes, but started to decrease in the second half of the rat exposure procedure. The levels of 5-HIAA also increased with the introduction of the rat, but this response was somewhat delayed as compared to the immediate 5-HT response. It is of interest to contrast the effects of the presence of the predator on hippocampal 5-HT with the behavioral changes concurrently taking place in the stressed mice. Immediately at the start of exposure to the rat, mice usually move to a corner of the cage and become highly vigilant. Next, various risk-assessment behaviors are initiated, such as sniffing the air, stretching towards and retracting from the separation wall (flat back posture) and then sniffing at the separation wall. During the second half of the predator exposure, mice were

seen to be extensively sniffing the bedding of their cage (Beekman *et al.*, 2005). From these results we concluded that during psychological stress 5-HT in the hippocampus increases especially during the initial phase, supporting the assessment of a new and potentially life-threatening situation and assuring adequate coping responses regarding the challenge. Increases in extracellular concentrations in 5-HT and 5-HIAA were also observed in the frontal cortex, the amygdala and lateral septum (Rueter and Jacobs, 1996; Beekman *et al.*, 2005).

Whereas the above-discussed predator stress paradigm is an example of a psychological form of stress, most stressors used to investigate the effect of stress on hippocampal 5-HT have combined psychological and physical aspects. Tail pinch (attaching a paper clip to the tail of a rat or mouse) causes arousal and also activates pain sensory pathways and consummatory behaviors. Microdialysis studies have shown that this form of stress results in increases in extracellular 5-HT in the

hippocampus, prefrontal cortex and amygdala, although in some studies this response was delayed until after termination of the stressor (Kalén *et al.*, 1989; Pei *et al.*, 1990; Vahabzadeh and Fillenz, 1994; Rueter and Jacobs, 1996; Fujino *et al.*, 2002). The delayed increase in 5-HT could well be caused by the increased consummatory and grooming behavior after the removal of the paper clip – a notion that may be underscored by the demonstration of a subset of 5-HT neurons which is highly active during oral–buccal movements in the cat (Fornal *et al.*, 1996), and by our own observation that grooming behavior in the home cage profoundly increases hippocampal 5-HT in rodents (Linthorst *et al.*, unpublished data). Electric foot- or tail-shock represents another example of a stressor with combined physical and psychological aspects. Surprisingly, there is not much information available regarding the effects of this stressor on extracellular levels of 5-HT in forebrain regions. *Post-mortem* tissue studies suggest that electrical foot-shock increases 5-HT turnover in the hippocampus, amygdala and prefrontal cortex (for references, see Linthorst, 2005). Interestingly, it seems that the exact response to electrical shock is dependent on the extent of control an animal can exert over the shock. Thus, an augmented turnover and extracellular response of 5-HT has been found in the frontal cortex and ventral hippocampus of rats for whom the shock was inescapable, as compared to their conspecifics that could escape the shock (Amat *et al.*, 1998; Heinsbroek *et al.*, 1991). Interestingly, the prefrontal cortex plays a key role in inhibiting the activation of serotonergic neurons in the DRN when rats are given the opportunity to escape shocks – i.e., when the stressor is controllable by the animal (Amat *et al.*, 2005). Conditioned fear stress also leads to an increase in hippocampal and prefrontal cortical extracellular levels of 5-HT, although the neurotransmitter response was not studied during the training phase when animals actually receive the electrical shocks (Yoshioka *et al.*, 1995; Wilkinson *et al.*, 1996; Hashimoto *et al.*, 1999). Importantly, Wilkinson and colleagues demonstrated that the 5-HT activation in the hippocampus induced by conditioned fear stress was due to the contextual aversive cues (i.e., the box in which the animal had received the shocks) but not to the conditioned discrete stimulus (Wilkinson *et al.*, 1996).

During the past years, we and others have extensively studied the effects of the combined psychological/physical stressor forced swimming on extracellular levels of 5-HT and 5-HIAA. Forced swim stress is performed by placing rats or mice in a glass beaker filled with water from which they cannot escape. Forced swim stress causes profound behavioral changes. During the swim session, animals will first try to escape by climbing against the wall and, in the case of rats, will explore possible escape routes under the water surface (diving). This

period is followed by swimming in the container and by floating behavior. Although increased floating behavior/immobility is used as an index for despair or depressed behavior in the Porsolt swim test, it is now increasingly seen as an index of a learning process – i.e., the animal learns a behavioral coping strategy aimed to conserve energy when forced to swim on a second exposure (De Pablo *et al.*, 1989; Abel, 1993; Korte, 2001; Bilang-Bleuel *et al.*, 2005; Chandramohan *et al.*, 2008). However, apart from increased motor activity during parts of this challenge, the physiology of the animals is compromised by a rapid and extensive loss of body temperature (Stone, 1970; Linthorst *et al.*, 2007) (see below). Fifteen minutes of forced swim stress at 25°C results in an immediate increase in hippocampal levels of 5-HT. This increase is followed by a return to pre-stress levels when animals are returned to their home cage, and a subsequent second rise in the neurotransmitter levels (Figure 2C). Interestingly, whereas swimming in warm water (35°C) causes a rapid and prolonged rise in hippocampal extracellular 5-HT (Figure 2E), no effect on 5-HT was found when the animals were forced to swim in cold water (19°C), although levels increased 15–30 minutes after the termination of the stressor (Figure 2A). The effects of forced swim stress on extracellular levels of 5-HIAA were also highly water-temperature-dependent. Thus, forced swim stress in water at 35°C causes an immediate and sustained increase in hippocampal extracellular 5-HIAA (Figure 2F). However, the levels of this metabolite actually first decrease significantly in rats forced to swim in cold water at 19°C, after which they increase gradually (Figure 2B) (Linthorst *et al.*, 2007). Using an *in vivo* biotelemetry approach, it was found that 15 minutes of forced swimming had minor effects on the body temperature of the rats when water of 35°C was used (a decrease of about 1°C). However, at 25°C and 19°C, rats lost, respectively, approximately 8°C and 12°C of body temperature (Figure 2) (Linthorst *et al.*, 2007). These observations, together with the microdialysis findings described above, have led us to postulate that the final outcome of the neurotransmitter response to stress is shaped by the combination of the psychological aspects of the stressor and the impact of the concurrent physical changes. Recent investigations into the effects of forced swim stress on extracellular levels of GABA in the hippocampus have further substantiated this hypothesis. Thus, forced swim stress at 35°C increased hippocampal levels of GABA, whereas swimming at 25°C led to a profound decrease in extracellular neurotransmitter concentrations in this brain structure (De Groote and Linthorst, 2007). The physical impact of forced swim stress may also explain why there are some conflicting results reported in the literature with regard to the effects of this stressor on hippocampal 5-HT. Thus, an

**Figure 2** Comparison of the effects of forced swim stress at different water temperatures – (A, B) 19°C; (C, D) 25°C; (E, F) 35°C – on core body temperature (closed triangles) and hippocampal extracellular levels of 5-HT and 5-HIAA (open triangles) in male Wistar rats. 5-HT and 5-HIAA levels were assessed by *in vivo* microdialysis and body temperature (in separate animals) by *in vivo* biotelemetry. Levels of 5-HT and 5-HIAA are expressed as percentage of baseline. The time points on the x-axis indicate the time of the day at which collection of the respective sample was started. After collection of nine 15-min baseline samples, rats were placed in a beaker glass with water for 15 min (at 11:15h, indicated by the arrow). After the forced swim session they were taken out of the water, dried with a towel and returned to their home cage, following which another fourteen 15-min dialysis samples were collected. 5-HT and 5-HIAA concentrations were analyzed by HPLC with electrochemical detection. Body temperature data were collected at 2-min intervals, but were averaged over 15-min bins to match the 15-min dialysate sample duration. Values are mean  $\pm$  SEM. For 5-HT and 5-HIAA  $n = 5-7$ ; for body temperature  $n = 6$ . Note that swimming for 15 min at 19 and 25°C produced a pronounced decrease in core body temperature and that the 5-HT and 5-HIAA responses in the hippocampus are dependent on the water temperature used. Comparison of the body temperature and neurotransmitter profiles suggests that two different processes may shape the ultimate 5-HT and 5-HIAA responses to swim stress. Thus, forced swimming causes an increase in extracellular levels of 5-HT and 5-HIAA, which is temporarily quenched or concentrations are transiently decreased when core body temperature falls below approximately 31°C. Reproduced from Linthorst *et al.* (2007), with permission of *Stress* (Informa Healthcare).

increase in hippocampal 5-HT was found by Rueter and Jacobs in rats that were forced to swim for 30 minutes in water of 30–35°C (Rueter and Jacobs, 1996), while Kirby and colleagues only observed a decrease in extracellular 5-HIAA (and no effect on 5-HT) when rats had to swim for 30 minutes in water of 21–22°C (Kirby *et al.*, 1995). Moreover, these authors found also disparate effects of swim stress in the frontal cortex and amygdala – i.e., increased levels or no effect/decreased levels of 5-HT and 5-HIAA (Kirby *et al.*, 1995; Rueter and Jacobs, 1996).

Immune stress is an example of a stressor with an immediate threat to the integrity and survival of an organism, and therefore is expected to merely be processed at the level of lower brain structures such as the hypothalamus and brainstem nuclei (Herman and Cullinan, 1997). However, we have provided extensive evidence that an immunological challenge impacts on serotonergic neurotransmission in the hippocampus of rats. Thus, systemic administration of bacterial endotoxin (lipopolysaccharide, LPS) results in a pronounced and prolonged (>6 hours) elevation of hippocampal extracellular levels of 5-HT and 5-HIAA (Linthorst *et al.*, 1995a). These effects can be mimicked by peripheral and intracerebroventricular administration of interleukin-1 $\beta$  and interleukin-2, but not by TNF- $\alpha$  (Linthorst *et al.*, 1995a; Merali *et al.*, 1997; Pauli *et al.*, 1998). Studies in rats treated chronically with CRF suggest that a full hippocampal 5-HT response is a prerequisite for the adequate development of sickness behavior during immune activation (Linthorst *et al.*, 1997). Based on these observations, we have concluded that immune stress also possesses a distinct psychological component probably involved in the mood changes occurring during infection.

### ***Hypothalamus and pre-optic area***

The hypothalamus and pre-optic area are key structures in the coordination of the HPA axis and the autonomic response to stress. Most studies using *post-mortem* tissues have demonstrated that stress increases or has no effect on the turnover of 5-HT in the different subnuclei of the hypothalamus (for references, see Linthorst, 2005). Surprisingly, there is little information available regarding the effects of stress on extracellular levels of 5-HT and 5-HIAA as assessed by *in vivo* microdialysis. We have studied the effects of immune stress on serotonergic neurotransmission in the pre-optic area of the rat. In contrast to the profound activation of 5-HT in the hippocampus as described above, no effect on extracellular 5-HT and only a minute rise in extracellular 5-HIAA was found in the pre-optic area (Linthorst *et al.*, 1995b). The absence of an effect of immune stress on pre-optic 5-HT

is underscored by similar observations made in the cat (Wilkinson *et al.*, 1991). In contrast, immune system activation was found to increase both extracellular 5-HT and 5-HIAA levels in the hypothalamus of the rat (Mohankumar *et al.*, 1993; Shintani *et al.*, 1993; Lavicky and Dunn, 1995). With respect to psychological stress, we have recently demonstrated that exposure to a predator increases extracellular levels of 5-HT and its metabolite in the paraventricular nucleus and anterior hypothalamus of Balb/c mice (Beekman and Linthorst, unpublished observations). Another form of psychological stress, immobilization, was also found to increase markedly the extracellular levels of 5-HT in the hypothalamus (Shimizu *et al.*, 1992; Shintani *et al.*, 1995), although only a marginal effect on 5-HIAA was found. Interestingly, these effects could be blocked by infusion of an IL-1 receptor antagonist (Shintani *et al.*, 1995). From the above, the general picture is emerging that stress increases extracellular 5-HT in the hypothalamus (but not the pre-optic area), while it is at the same time clear that more research (implementing both acute and chronic stress paradigms) will be needed to further substantiate this notion.

### ***Repeated and chronic stress***

In previous sections of this chapter we have given examples of studies demonstrating that repeated stress and stressors of a longer duration may change the electrophysiological properties of raphe 5-HT neurons and the synthesis of this neurotransmitter. However, similarly to 5-HT firing rate and synthesis, there is, unfortunately, only limited information available regarding the effects of repeated or chronic stress on extracellular levels of 5-HT and 5-HIAA. This may have to do with the complicating factor that microdialysis is normally performed over a restricted number of days. However, there are a few interesting studies which have investigated the status and responsiveness of the 5-HT system at the end of a chronic stress paradigm.

Under baseline conditions, extracellular levels of 5-HT are closely correlated with the vigilance state of the animal. Thus, in various brain structures, among them the hippocampus, highest levels of 5-HT are found during active waking, while levels decrease when animals are entering slow-wave sleep (Houdouin *et al.*, 1991; Imeri *et al.*, 1994; Portas and McCarley, 1994; Portas *et al.*, 1998; Park *et al.*, 1999; Shouse *et al.*, 2000; Python *et al.*, 2001; Peñalva *et al.*, 2003). Interestingly, extracellular levels of 5-HT are lowest during rapid eye movement sleep, probably caused by the almost complete silencing of the firing rate of raphe 5-HT neurons during this sleep stage. In a combined *in vivo* microdialysis/sleep EEG study, we found that during a longer period of stress

(i.e., a 4-hour period of sleep deprivation), hippocampal 5-HT levels are increased throughout the whole period (Peñalva *et al.*, 2003). However, after termination of the sleep-deprivation procedure, hippocampal levels of 5-HT decrease during the rebound phase and the normal 5-HT/sleep stage relationship is immediately re-established. Of interest in this respect is a recent study demonstrating that a chronic mild stress paradigm is able to disrupt exactly this tight relationship between hippocampal 5-HT levels and sleep stage by an as yet unknown mechanism (Gronli *et al.*, 2007).

Another example of the effects of chronic stress on 5-HT levels is the isolation-rearing model, as developed by Charles Marsden. These authors have studied the behavioral and neurochemical consequences of isolation rearing – i.e., single housing of rats for 6 weeks immediately following weaning – as compared to social, group housing. Isolation induces profound behavioral changes in the animals, but no changes in baseline 5-HT levels in the dorsal hippocampus were observed. However, the 5-HT system is clearly compromised in isolation-reared rats when challenged with a stress paradigm. Thus, foot-shock stress and stress caused by placing the animal on an elevated x-maze both result in a rise in hippocampal 5-HT in group-reared rats, but have no effect in isolated rats (Bickerdike *et al.*, 1993; Muchimapura *et al.*, 2002). There are some indications that the effects of chronic stress on extracellular 5-HT may be stressor-dependent. Repeated exposure of rats to an elevated open platform not only increased extracellular levels of 5-HT and 5-HIAA in the dorsal hippocampus under baseline conditions, but also resulted in elevated 5-HT levels when animals were tested on day 10 of the repeated platform exposure; this as compared to naïve animals which showed no changes in hippocampal 5-HT when placed on the elevated open platform for the first time (Storey *et al.*, 2006).

### Effects of stress on serotonergic neurotransmission in animal models of aberrant HPA axis functioning

As discussed above, changes at the level of the genome may be implicated in the etiology of stress-related psychiatric disease. Mutant mouse strategies may therefore represent a useful tool to further study the regulation of the stress response and, importantly, to gain insight into (malfunctioning) stress coping mechanisms. Based on the putative involvement of the CRF system in depression and anxiety, and our observation that long-term elevation of brain CRF levels precipitate altered responsiveness of hippocampal 5-HT to stress (Linthorst *et al.*, 1997), we became interested in studying a genetic mouse model of CRF1 impairment (Timpl *et al.*, 1998). Performance of

*in vivo* microdialysis in freely behaving CRF1 knockout mice over the diurnal cycle demonstrated that deletion of CRF1 results in significantly elevated levels of 5-HIAA, but not of 5-HT, in the hippocampus during both the light and dark periods (Peñalva *et al.*, 2002). There is substantial evidence that 5-HIAA levels may be an indicator for newly-synthesized 5-HT which has not been released from the presynaptic element (Grahame-Smith, 1974; Kuhn *et al.*, 1986; Peñalva *et al.*, 2002). Thus, the increased levels of 5-HIAA suggest that the synthesis of 5-HT is increased (in the hippocampus) in CRF1 knockout mice. Naturally, the question arises whether the deletion of CRF1 also has consequences for the response of serotonergic neurotransmission to stress. To address this question, CRF1 knockout and wild-type mice were subjected to a 10-minute session of forced swim stress (25°C). Interestingly, although the 5-HIAA response is similar in both genotypes, CRF1 knockout mice show an augmented 5-HT increase in the hippocampus when subjected to this form of stress (Peñalva *et al.*, 2002). To the best of our knowledge, this is the only information available on extracellular 5-HT and 5-HIAA in a mutant mouse model with alterations at the level of the CRF system. Together with the pronounced effects of CRF and the urocortins on hippocampal 5-HT and 5-HIAA levels demonstrated after intracerebroventricular administration (De Groote *et al.*, 2005), these data clearly show the intricate relationship between the CRF and 5-HT systems; aberrant functioning of this relationship may therefore underlie the development of certain psychiatric diseases.

Apart from changes in CRF, changes in GR and at the level of the mineralocorticoid receptor, both critical in the regulation of the HPA axis, may also play a role in stress-related mental health disorders. In an earlier study we investigated the stress responsiveness of GR-impaired mice with respect to behavior, HPA axis activity and hippocampal serotonergic neurotransmission (Linthorst *et al.*, 2000). Exposure of GR-impaired mice to a predator (rat; see above) resulted in an abnormal behavioral response to this potentially life-threatening stressor. GR-impaired mice showed abnormal risk assessment behaviors (i.e., an immediate inspection of the separation wall) which was accompanied by an absent HPA axis response to this challenge. Interestingly, during predator stress an augmented rise in 5-HT levels in the hippocampus in GR-impaired mice was found. Thus, although impairment of GR did not lead to changes in baseline levels of 5-HT and 5-HIAA, the response of this neurotransmitter to psychological stress was clearly exaggerated (Linthorst *et al.*, 2000). Alterations in serotonergic neurotransmission have also been found in other HPA axis-related mutant mice (Wei *et al.*, 2004; Rozeboom *et al.*, 2007), but unfortunately these studies were limited to the measurement of 5-HT<sub>1A</sub>

receptor mRNA expression, and to date no studies on the extracellular levels of 5-HT and its metabolite in these mouse lines have been published.

### Enhanced stress coping by exercise

As put forward in the introduction of this chapter, understanding how stress affects serotonergic neurotransmission is essential for increasing our insight into the mechanisms underlying stress-related psychiatric disease. However, equally important will be a further understanding of factors and mechanisms promoting adequate psychological and physiological coping with stress. There is now abundant evidence demonstrating that moderate exercise has beneficial effects on the cardiovascular system, on weight and food intake control and on sleep profiles (Lancel *et al.*, 2003). Moreover, during the past few years we have provided extensive evidence showing that voluntary exercise (i.e., wheel running in rats and mice that have access to a running wheel in their home cage) increases the flexibility of the HPA axis response to a stressful situation (Droste *et al.*, 2003, 2007). Thus, when corticosterone is needed to mobilize energy during a stressor with physical impact, such as during forced swimming, the plasma response of this stress hormone is markedly enhanced as compared to the response in sedentary animals. In contrast, during a mild psychological stressor, such as exposure to a novel environment, the plasma corticosterone response is significantly reduced in exercised rats and mice (Droste *et al.*, 2003, 2007). Interestingly, the lower plasma corticosterone response correlates with less anxious and risk-assessment behaviors during the period of exposure to novelty, suggesting a better behavioral and physiological coping with the stressful challenge in exercised animals (Droste *et al.*, 2007; Collins *et al.*, 2009). The notion that the dynamics of the HPA axis may be increased in exercising subjects is also underscored by an increased amplitude in the ultradian rhythm of free corticosterone (as assessed by *in vivo* microdialysis; see Droste *et al.*, 2008; Linthorst and Reul, 2008) in exercised rats as compared to sedentary control animals in the hours before the start of the active period (Droste *et al.*, 2009). The above described evidence clearly supports a beneficial role of exercise in the regulation of physiological parameters, but, also for the purpose of this chapter, the logical next question would be whether exercise also supports mental health and, if so, which neurotransmitter pathways would be involved. Although exercise is increasingly being prescribed as a co-treatment for a number of psychiatric illnesses, its scientific underpinning needs to be strengthened. We have demonstrated that exercised mice show reduced anxiety and less impulsivity in a number of

behavioral tests (Binder *et al.*, 2004b). Moreover, exercised rats show profound alterations in the expression of GABA-A receptor subunits in the brain (Hill *et al.*, 2008), which is of interest given that GABA-A receptors are an important drug target for the treatment of stress-related psychiatric disease. But what about 5-HT? Unfortunately, research on the effects of exercise on serotonergic neurotransmission in higher limbic brain regions has mainly been conducted using a forced running paradigm – i.e., forcing rodents to run on a treadmill. This paradigm causes stress in rodents, as it is usually performed during the light period – i.e., the period when the animals would normally rest and sleep. With this caveat in mind, treadmill experiments indicate that exercise may increase 5-HT and 5-HIAA levels in various brain structures (Meeusen *et al.*, 1996; Wilson and Marsden, 1996; Gomez-Merino *et al.*, 2001), which would fit with the observation that there is a close relationship between extracellular levels of 5-HT and vigilance state (with highest levels attained during active waking), as described above. Interestingly, recently increased expression of TPH2 mRNA in the DRN and MRN at zeitgeber time 10 (but not at zeitgeber time 2) has been described in rats after voluntary wheel running for 6 weeks (Malek *et al.*, 2007). Moreover, voluntary exercise significantly reduces the levels of 5-HT transporter mRNA in the DRN and MRN after 3 and 6 weeks (Greenwood *et al.*, 2005). However, from the limited available information, it is clear that, for a better understanding of the beneficial effects of exercise on mood, affect and anxiety, it will be of critical importance to further study the impact of exercise on the 5-HT system (and on other neurotransmitter systems including GABA) during voluntary exercise and using an *in vivo* microdialysis paradigm.

### Concluding remarks and future

As reviewed in this chapter, the current state of our knowledge on the relationship between stress and the 5-HT system clearly shows that this neurotransmitter system is highly responsive to acute forms of stress, albeit in a stressor-dependent and brain region-specific manner. Without doubt, the available information on the consequences of chronic stress on serotonergic neurotransmission is limited, and no firm conclusions can be drawn. In our opinion it will be of great importance to further elucidate the effects of stress on the 5-HT system with more attention to the impact of chronic stress and to the mechanisms underlying putative alterations in serotonergic neurotransmission. Studies implementing the 5-HT system in exercising subjects will be needed to further increase our knowledge on how to improve stress coping

mechanisms, and will contribute to our understanding of how to increase stress resilience in people suffering from stress in today's hectic and stressful world.

# The Role of Serotonin in Depression

Gregory V. Carr and Irwin Lucki\*

*Departments of Psychiatry and Pharmacology, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania*

**Abstract:** A substantial body of research has developed concerning the role of serotonin (5-HT) in the etiology and treatment of major depressive disorder (MDD). The first section of this chapter summarizes the clinical evidence implicating alterations of the serotonergic system in the etiology of MDD. A general serotonin vulnerability has been proposed as a major risk factor in MDD, consisting of the composite risk factors from different components of 5-HT transmission. The effects of abnormal 5-HT synthesis, receptor function and genetic polymorphisms are discussed. The second section reviews some of the preclinical models and tests that are used to measure depressive behaviors and the efficacy of antidepressant drugs, such as selective serotonin reuptake inhibitors (SSRIs). This section is focused on models that are commonly used in rodent species. Models and tests that require either acute or chronic antidepressant administration to achieve behavioral alterations are covered. The third section reviews the preclinical (rodent) literature concerning the role of individual 5-HT receptors in the development and pharmacological treatment of depressive behaviors. The effects of 5-HT depletion and of manipulation of the 5-HT transporter are also discussed. Although identifying the 5-HT receptors that support the therapeutic effects of SSRIs may lead to the development of more effective antidepressant drugs with fewer side effects, it is unclear whether the complete antidepressant effect of SSRIs can be reproduced by a single selective 5-HT receptor agonist or antagonist.

**Keywords:** depression, antidepressants, SSRIs, models of depression, knockout mice, serotonin, rat, psychiatry.

## Introduction

Since the identification of iproniazid, an early antidepressant, as a monoamine oxidase inhibitor (MAOI) that prevents the degradation of serotonin (5-HT), the role of the serotonergic system in the etiology and treatment of depression has been an intense area of study. In the years since this discovery, many advances have been made in our understanding of the components of the serotonergic system. At least 14 serotonin receptor subtypes belonging to seven major families have been identified in the brain, each associated with distinct topographical distributions and cell signaling mechanisms. The nuclei of serotonin-producing neurons in the hindbrain and mid-brain have been identified, and their axonal projections have been mapped (Barnes and Sharp, 1999). In addition to detailed molecular and anatomical information, there is a large body of behavioral and pharmacological data that has served to solidify the link between different components of the 5-HT system and depressive behavior.

This chapter will consider in turn the roles for 5-HT in causing major depressive disorder (MDD) and the role of 5-HT mechanisms underlying therapeutic treatment. Efforts to attribute the cause of depression to deficient 5-HT transmission stem from a historical literature that measured changes in the metabolism of 5-HT in patients with MDD. More sophisticated techniques are now available for clinical studies that have allowed the association of MDD with specific genes related to a family of 5-HT-related targets, and the imaging of specific 5-HT receptors in patients. This literature will be reviewed in brief because it is too large to be contained in this chapter.

Among the frontline class of antidepressant treatments, selective serotonin reuptake inhibitors (SSRIs) exhibit their primary pharmacological effects through manipulation of the 5-HT system. SSRIs produce many adaptations that may be involved in their clinical efficacy. Preclinical studies have attempted to identify particular 5-HT receptor subtypes associated with antidepressant behavioral responses, with the goal of eventually providing targeted treatments. Genetically modified animals have been studied as models of developmental genetic vulnerability, and

to elucidate the mechanism of action of SSRIs. This literature will be covered in the second part of this chapter.

### Serotonin in the etiology of depression

A variety of evidence has accumulated suggesting that deficits in 5-HT neurotransmission can contribute to the development of MDD. The earliest evidence reported decreased levels of 5-HT metabolites in the cerebrospinal fluid (CSF) of depressed patients, but much of the association may actually have been based on suicidal behavior rather than depression (Asberg, 1997; Placidi *et al.*, 2001). Also, several reports found that the availability of L-tryptophan in plasma was significantly lower in subjects with MDD (Cowen *et al.*, 1989; Maes *et al.*, 1990), suggesting an overall reduction of 5-HT metabolism. Depletion of tryptophan, and lowering of brain 5-HT, can cause transient depressive symptoms in individuals that are vulnerable to depression, based on their personal or family history of depression (Moreno *et al.*, 1999; Neumeister *et al.*, 2004). In recently remitted depressed patients receiving SSRIs, acute tryptophan depletion led to a rapid clinically significant return of depressive symptoms (Delgado *et al.*, 1999). In contrast, remitted depressed patients maintained with tricyclic antidepressants were less prone to relapse following tryptophan depletion. Although these findings suggested that the synthesis of 5-HT is necessary for the maintenance of remission induced by SSRIs, they are also consistent with the evocation of transient withdrawal symptoms following chronic SSRI treatment.

Another strategy to assess serotonergic vulnerability has been used in studies that measured HPA-axis hormone secretion following the administration of 5-HT precursors, drugs that stimulate 5-HT release or directly activate 5-HT receptors (Maes and Meltzer, 1995). In particular, 5-HT<sub>1A</sub>, 5-HT<sub>2A</sub> and 5-HT<sub>2C</sub> receptors stimulate cortisol and prolactin secretion in man. In patients with MDD, blunted prolactin responses appear to support evidence for decreased function of 5-HT<sub>1A</sub> receptors and enhanced cortisol responses for enhanced function of 5-HT<sub>2A</sub> and 5-HT<sub>2C</sub> receptors.

Patients with MDD have been studied at autopsy using histological methods to measure changes in brain 5-HT receptors. Reliable assessment of neurochemicals after autopsy is subject to variability from the use of different laboratory techniques, the *post-mortem* interval, heterogeneity of diagnoses and the uncontrolled use of accompanying medications. A reduction of serotonin transporter sites has been reported in the prefrontal cortex of depressed patients, possibly representing widespread impairment of serotonergic function (Arango *et al.*, 2002). This finding may be accompanied by decreased 5-HT<sub>1A</sub> and increased

5-HT<sub>2A</sub> receptor binding sites found in deceased depressed patients (Stockmeier, 2003).

Although lacking the resolution of histology, imaging studies using positron emission tomography can be used to measure serotonergic targets in MDD (Stout *et al.*, 1996; Stockmeier, 2003; Meyer, 2007). These studies can also control patient selection and medication status. Binding potential for 5-HT transporters has been reported to be elevated in MDD (Cannon *et al.*, 2007; Meyer, 2007). However, there does not appear to be a longstanding change in 5-HT transporter binding potential in recovered medication-free MDD patients (Bhagwagar *et al.*, 2007), indicating normalization with resolution of MDD. Several studies have reported reduced binding potential for 5-HT<sub>1A</sub> receptor imaging ligands in depressed patients (Drevets *et al.*, 2007). The detection of similar findings in unmedicated (Hirvonen *et al.*, 2008) and remitted depressed individuals (Bhagwagar *et al.*, 2004) support suggestions that reduced 5-HT<sub>1A</sub> receptor activity is a trait marker associated with MDD. The binding potential for cortical 5-HT<sub>2A</sub> receptors was reported decreased (Stockmeier, 2003) or increased in unmedicated depressed patients (Meyer *et al.*, 2003), depending on medication history, and remained elevated in unmedicated recovered patients when compared with controls (Bhagwagar *et al.*, 2006).

The family of genes that regulate 5-HT transmission or 5-HT receptors has been reported to be associated with MDD or with the therapeutic effects of SSRIs. Several genes for the 5-HT transporter or 5-HT receptors are distributed widely in more than one form across the human population, and they are associated with variations in 5-HT function. The most widely known polymorphism involves the insertion/deletion of either a 528-base pair sequence (long form) or a 484-base pair sequence (short form) within the promoter region of the 5-HT transporter (Lesch *et al.*, 1996). The long form is associated with greater transcription and function. There are many studies that have examined the occurrence of 5-HT transporter polymorphisms with depression and anxiety (Jans *et al.*, 2007), and the short-allele has been associated with depression, anxiety and aggression (Lesch *et al.*, 1996; Lesch, 2001). The 5-HT<sub>1A</sub> receptor is a key regulator of 5-HT transmission because the presynaptic 5-HT<sub>1A</sub> receptor regulates neuronal discharge and negative feedback while the postsynaptic 5-HT<sub>1A</sub> receptor is located in key limbic regions involved in affective behavior. A common polymorphism in the human 5-HT<sub>1A</sub> promoter region has been identified and was associated with depression and suicide (Le Francois *et al.*, 2008). A polymorphism was identified in the *hph2* gene that regulates the synthesis of serotonin and was associated with depression (Zhang *et al.*, 2005), although this was not replicated in a broader sample of depressed patients (Glatt *et al.*, 2005; Van Den Bogaert

*et al.*, 2005; Zhou *et al.*, 2005). In addition to providing vulnerability for depression and anxiety disorders, several 5-HT genes have been associated with the therapeutic efficacy of SSRIs. Thus, 5-HT transporter polymorphic variations in alleles for the 5-HT transporter, 5-HT<sub>1A</sub> receptor and 5-HT<sub>2A</sub> receptors have been associated with rates of recovery for SSRIs in treating depression in some studies (Serretti and Artioli, 2004; McMahon *et al.*, 2006; Lekman *et al.*, 2008; Lin and Chen, 2008). Thus, the family of genes related to 5-HT transmission may serve either as endogenous markers of vulnerability for depression and anxiety or as pharmacogenetic indicators of therapeutic efficacy.

It is unlikely that any one patient would show dysfunction of all of the components of 5-HT transmission reported to be altered in MDD. Rather, a general serotonin vulnerability has been proposed as a major risk factor in MDD. Thus, patients may be vulnerable for developing MDD from a composite of individual risk factors associated with the many functional components of 5-HT transmission (Jans *et al.*, 2006). Similarly, therapeutic effectiveness may rely on a composite of 5-HT receptors distributed throughout the brain, rather than on the activity of a single 5-HT receptor in a single locus. The evidence indicates that more than a single type of 5-HT receptor is likely to be involved in producing the behavioral effects of SSRIs.

### Behavioral pharmacology of antidepressant drugs

This section will focus on behavioral pharmacology studies in rodents that have helped to determine the role of components of the 5-HT system that are involved in treating depression. First, animal models and tests of depression and antidepressant activity that have been used to identify the neurobiological effects of clinically effective antidepressants will be reviewed. Second, the roles of serotonergic mechanisms, including the activation or blockade of individual 5-HT receptors, will be summarized in relation to the animal behavior tests. Over the years, a number of ligands for 5-HT receptors, both agonists and antagonists, have been developed as pharmacological tools in order to delineate the respective contributions of the receptor subtypes. Also, the incorporation of knockout (KO) mice into behavioral pharmacology has generated a wealth of insight into the roles of individual receptors in a number of different behaviors. To this end, numerous 5-HT receptor KO mice have been used to investigate the etiology of depression-like behavior. These studies will also be covered in this section. For a comprehensive review of 5-HT receptors and signaling mechanisms, see Barnes and Sharp (1999).

### Animal tests and models of depression

This section will divide animal tests into two types, based on the time-course for the effects of antidepressant compounds in the respective tests and models. First, behavioral tests in which an antidepressant-like effect is evident after a single or small number of administrations will be discussed. The second part will discuss the tests and models that require chronic treatment (>2 weeks) with antidepressants in order to display efficacy.

#### Acute tests

##### *Forced swim test (FST)*

The FST was developed by Porsolt and colleagues as a way to measure the effects of antidepressant compounds in rats and mice (Porsolt *et al.*, 1977). The test involves placing the rodent in a container of water (usually cylindrical) from which the subject is unable to escape. After a period of time in which the subject attempts to escape from the container, the subject adopts a posture of immobility. Immobility is characterized by the lack of movement except that which is necessary to keep the subject's nose above the water level. In rats, the test consists of two swim exposures. The first is a 15-minute exposure. The second, conducted 24 hours later, is a 5-minute exposure. Immobility time is recorded during the second 5-minute test. In mice, the procedure consists of a single 6-minute test (Porsolt *et al.*, 1978). In the FST, antidepressants cause a decrease in immobility time at doses that do not increase general locomotor activity, unlike psychomotor stimulants (e.g., amphetamine, cocaine), which decrease immobility at doses that increase general locomotor activity.

Motivated by the inability of this test to measure the effects of SSRIs, changes in the procedure and scoring of the FST were introduced by Lucki and colleagues as the modified rat FST (Detke *et al.*, 1995a). This version of the FST introduced a set of changes that served to increase the utility of the test. The most important modifications were the switch to identification of component active behaviors along with immobility, the original FST scored only the total duration of immobile time. In the modified rat FST, the frequency of immobility, swimming and climbing is measured over the 5-minute test (Detke *et al.*, 1995a). Swimming is defined as horizontal movement throughout the chamber, and climbing is defined as vertical movement of the forepaws directed towards the sides of the chamber. Serotonergic antidepressants, including SSRIs, selectively increase swimming behavior. This effect was difficult to measure under the test conditions usually used for the original version of the FST.

In addition, the modified rat FST is able to differentiate between antidepressants that work through serotonergic mechanisms or noradrenergic mechanisms, as noradrenergic compounds selectively increase climbing behavior compared to the increase in swimming behavior seen with serotonergic compounds. Many laboratories have now adopted this scoring system (Cryan *et al.*, 2005).

#### *Tail suspension test (TST)*

The TST is a test of antidepressant activity in mice that shares its experimental rationale with the FST (Steru *et al.*, 1985). In the test, mice are suspended from a lever by their tails and their behavior is recorded over a 6-minute time period. As in the FST, mice struggle to escape for a period of time and then adopt a posture of immobility. The time spent immobile is the dependent measure. As in the FST, antidepressants decrease the amount of time spent immobile without increasing general locomotor activity.

#### *Learned helplessness (LH)*

LH is characterized by the inability of a subject to terminate a controllable stressor by performing a behavior after having been exposed to an uncontrollable stressor (usually foot-shock) (Seligman *et al.*, 1975). LH is thought to simulate many of the symptoms of depression (Seligman *et al.*, 1975). Treatment with antidepressants decreases the escape latency and escape failures in the test after exposure to LH (Leshner *et al.*, 1979; Sherman and Petty, 1980).

### ***Chronic tests and models***

The next set of tests and models requires chronic treatment with antidepressants in order to induce a change in behavior. These tests are of particular interest to researchers because SSRIs usually require chronic treatment before they produce their clinical effects in depression or anxiety disorders.

#### *Novelty suppression of feeding (NSF)/Novelty-induced hypophagia (NIH)*

The NSF and NIH tests are unique among anxiety tests in that they respond to treatment with antidepressants (Bodnoff *et al.*, 1988; Dulawa *et al.*, 2004). This fact makes them extremely valuable tools in drug discovery, because antidepressants are effective against, and widely prescribed for, anxiety disorders.

Both the NSF and NIH tests are conflict-based anxiety tests. They take advantage of rodent species' natural aversion to bright, open spaces. The measures of anxiety in these tests are the latency to consume food and the amount of food consumed in the novel arena. The differences

between the two tests are that the NSF test uses standard chow and food deprivation in order to drive consumption in the novel arena, and the NIH test uses palatable foods (sweetened) consumed without food deprivation (Dulawa and Hen, 2005). This modification in the NIH procedure removes potential confounds caused by deprivation stress. Consumption in the novel arena is compared to the consumption levels in the home cage. The novel arena is brightly lit, and structurally different from the subject's home cage. Untreated subjects demonstrate a dramatic decrease in consumption in the novel arena compared to their home-cage consumption. Anxiolytics, such as benzodiazepines, decrease novel arena latency and increase novel arena food consumption without altering home-cage behavior. Antidepressant drugs, when administered chronically, are also able to produce an anxiolytic effect in these tests.

#### *Chronic mild stress (CMS)*

The rationale for the CMS model is that increased exposure to stressors, particularly unpredictable and uncontrollable stressors, increases the likelihood that a person will develop depression. In order to reproduce this in the laboratory, researchers typically use a set of mild stressors (e.g., strobe lighting, soiled cages, 24-hour lighting) administered in a semi-random fashion in order to mimic the stress of everyday life (Willner, 1997, 2005). A number of groups have been able to show that when administered over a period of weeks, the CMS procedures can lead to behavioral and endocrine changes that appear to be similar to human depression. The most common behavioral output measured during CMS experiments is the presence of anhedonia, represented as a decrease in consumption of a sucrose solution. However, changes in FST behavior, sleep alterations and locomotor activity suggest that the pathological changes resulting from CMS are more comprehensive than just alterations in a single endophenotype (Willner, 2005).

The alterations caused by CMS can be reversed by chronic treatment with a number of antidepressant drugs. Another feature that makes CMS an intriguing model is the fact that not all subjects exposed to CMS show a pathological change in behavior, and not all CMS-responsive subjects show a reversal after treatment with antidepressants (Jayatissa *et al.*, 2006). These features are present in human depression, and provide opportunities for research into the neural underpinnings of stress and treatment resistance. A major hindrance to the universal application of CMS in depression research is the difficulty with inter-lab reproducibility. A number of labs have been successful in the utilization of CMS, but many others have had difficulty implementing the procedure. This may be due to the lack of a standardized stress protocol, but it may also

be due to unavoidable differences in animal husbandry (e.g., colony room space/size, ventilation) and other issues between institutions (Cryan and Slattery, 2007).

#### *Olfactory bulbectomy (OB)*

Bilateral removal of the olfactory bulbs causes severe behavioral and endocrine changes in rodents (Song and Leonard, 2005). The most common behavioral change monitored in the OB model is hyperactivity in an open-field apparatus. These changes can be reversed by chronic antidepressant drug treatments. These pathological changes are not due purely to the anosmia caused by removal of the olfactory bulbs, since peripheral blockade does not result in an analogous syndrome. There are morphological changes to areas of the limbic system, such as the piriform cortex, that may underlie the effects of the OB procedure (Jarosik *et al.*, 2007).

### **5-HT system and antidepressant responses**

The current frontline treatments for depression in humans are the SSRIs. Consequently, these compounds have been tested extensively in rodents. This section will review not the vast number of studies utilizing these compounds alone, but rather the studies that attempt to identify the underlying components of the antidepressant response elicited by the SSRIs. The effects of 5-HT depletion on subsequent treatment effects, the role of individual 5-HT receptors and recent studies of rodents with targeted genetic mutations will be considered. These studies are summarized in Table 1.

#### **5-HT depletion**

Pharmacological depletion of 5-HT, by administration of the tryptophan hydroxylase (TPH) inhibitor parachlorophenylalanine (pCPA), does not produce effects on baseline behavior of antidepressant tests in rats or mice (Page *et al.*, 1999; Gavioli *et al.*, 2004; O'Leary *et al.*, 2007). pCPA did increase immobility of female 5-HT<sub>1B</sub> knock-out mice because of their high baseline levels of extracellular 5-HT (Jones and Lucki, 2005a). Mice generated with genetic deletion of the isoforms of TPH, either the major isoform in brain (TPH2) or a double knockout of both isoforms (TPH1 and TPH2), have been examined in tests for depression-related behavior (Savelieva *et al.*, 2008). Mice with complete deletion of TPH (TPH1 and TPH2) showed complete depletion of brain 5-HT from deletion of both TPH isoforms, and were significantly more immobile in the TST. TPH2 KO mice, with a substantial

but incomplete depletion of 5-HT, also demonstrated increased TST immobility, but only after repeated testing. Although FST immobility was increased in both sets of mice, this was caused by their inability to swim. A TPH2 knock-in mouse line with reduced TPH2 activity and an 80 percent reduction in brain 5-HT was also reported to have significantly increased immobility times in the TST (Beaulieu *et al.*, 2008). The presence of a depressive behavioral phenotype in the genetic models may be due to the role of 5-HT in development. Considering the accumulating evidence for associating 5-HT insufficiency with vulnerability to depression in humans, these latter genetic preparations provide the first evidence in animals for a pathological role of 5-HT depletion in depressive behavior.

Depletion of 5-HT with pCPA blocks the effects of fluoxetine in the FST and the TST, while the effects of desipramine are unaffected by 5-HT depletion (Cesana *et al.*, 1993; Page *et al.*, 1999; Gavioli *et al.*, 2004; O'Leary *et al.*, 2007). These effects demonstrate that serotonergic mechanisms underlie the acute behavioral effects of SSRIs on tests of depressive behavior. These effects in rodents correspond with a similar pattern of relapse induction in clinical patients following the depletion of serotonin or catecholamines. Patients treated with SSRIs will relapse temporarily if 5-HT is depleted by restricting 5-HT synthesis, but not by catecholamine depletion; patients treated with tricyclics demonstrate the complementary pattern of response to relapse induction (Delgado *et al.*, 1991; Delgado, 2004). These studies affirm the importance of changes in 5-HT neurotransmission in contributing to the effects of antidepressant treatments.

#### **5-HT<sub>1A</sub> receptor**

There is a large body of evidence that 5-HT<sub>1A</sub> receptor agonists produce antidepressant-like effects (Table 1) across a number of different tests in animals (De Vry, 1995; Blier and Ward, 2003). A number of 5-HT<sub>1A</sub> agonists decrease immobility in the rat FST (Kostowski *et al.*, 1992; Singh and Lucki, 1993; Lucki *et al.*, 1994). Also, the effects of 5-HT<sub>1A</sub> agonists, along with the effects of the antidepressants buspirone and desipramine, in the FST are blocked by pretreatment with 5-HT<sub>1A</sub> antagonists (Detke *et al.*, 1995b). The agonist MKC-242 produces antidepressant (AD)-like effects in the mouse FST even when 5-HT-producing neurons are destroyed or 5-HT synthesis is inhibited. This suggests that the AD-like effects of 5-HT<sub>1A</sub> receptor agonists are due to activation of postsynaptic 5-HT<sub>1A</sub> receptors (Matsuda *et al.*, 1995). These effects are not confined to the FST. Alnespirone and VN2222, a 5-HT<sub>1A</sub> agonist and a mixed

reuptake inhibitor and 5-HT<sub>1A</sub> agonist respectively, have been shown to produce AD-like effects in the LH paradigm (MacSweeney *et al.*, 1998; Tordera *et al.*, 2002). Flesinoxan produced AD-like effects in the OB model (Cryan *et al.*, 1997). Also, chronic treatment with the partial agonist buspirone produced AD-like effects in the CMS paradigm (Przegalinski *et al.*, 1995). The 5-HT<sub>1A</sub> receptor agonist 8-OH-DPAT also increases neurogenesis and survival of new neurons in the dentate gyrus after chronic treatment (Banasr *et al.*, 2004), effects produced by other clinically active ADs. Nevertheless, with the

exception of buspirone and gepirone, the development of 5-HT<sub>1A</sub> receptor agonists as antidepressants has not been clinically successful (Blier and Ward, 2003).

Clinically active AD treatments modify the response of 5-HT<sub>1A</sub> receptors in a number of brain regions. It has been postulated that desensitization of 5-HT<sub>1A</sub> autoreceptors after chronic treatment with antidepressant drugs is a key factor in antidepressant efficacy, and can account for the delay between the commencement of treatment and the alleviation of depressive symptoms (Piñeyro and Blier, 1999). In contrast, chronic administration of

antidepressant treatments facilitates transmission mediated by 5-HT<sub>1A</sub> receptors in postsynaptic regions, like the hippocampus (Burnet *et al.*, 1995; Haddjeri *et al.*, 1998; Shen *et al.*, 2002). Because antagonism of 5-HT<sub>1A</sub> autoreceptors in the raphe nuclei could facilitate AD-like effects through disinhibition of 5-HT release, 5-HT<sub>1A</sub> receptor antagonists were proposed as a promising adjunct to traditional AD treatment (Artigas *et al.*, 1996).

5-HT<sub>1A</sub> KO mice have been generated and studied by multiple labs (Heisler *et al.*, 1998; Parks *et al.*, 1998). Loss of the 5-HT<sub>1A</sub> receptor results in an antidepressant-like and anxiogenic phenotype (Heisler *et al.*, 1998; Parks *et al.*, 1998; Zhuang *et al.*, 1999; Jones and Lucki, 2005b). This lifelong phenotype is caused by the loss of the 5-HT<sub>1A</sub> receptor during early development in the rodent (Gross *et al.*, 2002). Although 5-HT<sub>1A</sub> KO mice exhibit normal basal and K<sup>+</sup>-evoked release of 5-HT, the absence of 5-HT<sub>1A</sub> autoreceptors causes an exaggerated increase of 5-HT levels in response to fluoxetine (Knobelman *et al.*, 2001). Nevertheless, 5-HT<sub>1A</sub> KO mice demonstrate refractory behavioral responses to acute or chronic SSRI treatment, probably because of the absence of postsynaptic 5-HT<sub>1A</sub> receptors (Mayorga *et al.*, 2001; Santarelli *et al.*, 2003). A polymorphic allele in the 5-HT<sub>1A</sub> receptor promoter region in humans has been identified as a risk allele for depression and anxiety disorders, and resistance to the effects of SSRIs (Le Francois *et al.*, 2008).

### 5-HT<sub>1B</sub> receptor

The 5-HT<sub>1B</sub> receptor is regulated by exposure to behavioral tests for antidepressants and following chronic antidepressant treatments. The stress of the LH procedure causes an up-regulation of the 5-HT<sub>1B</sub> receptor in the cortex, hippocampus, septum and dorsal raphe (Edwards *et al.*, 1991; Neumaier *et al.*, 1997). Chronic AD treatment decreases the mRNA of the 5-HT<sub>1B</sub> receptor in the dorsal raphe and decreases the efficacy of 5-HT<sub>1B</sub> autoreceptors, which may lead to an increase in 5-HT release (Neumaier *et al.*, 1996; Piñeyro and Blier, 1999; Anthony and Sexton, 2000; Gur *et al.*, 2000). 5-HT<sub>1B</sub> heteroreceptors in the dentate gyrus appear to contribute to increases of neurogenesis, a marker of AD treatment (Banasr *et al.*, 2004). Also, up-regulation of p11, a protein that increases 5-HT<sub>1B</sub> receptor function in a number of brain regions, reduces depression-like symptoms (Svenningsson *et al.*, 2006).

The actions of ligands at the 5-HT<sub>1B</sub> receptor produce results that correspond with the changes in the receptor seen after stress and AD treatment (Table 1). The agonist TFMPP, given systemically and locally within the ventral tegmental area (VTA), blocks the effects of desipramine in the rat FST (Cervo *et al.*, 1989).

5-HT<sub>1B</sub> receptor antagonists have been shown to produce AD-like effects and augment the effects of traditional ADs in the FST (Hogg and Dalvi, 2004; Tatarczynska *et al.*, 2004; Dawson *et al.*, 2006).

A 5-HT<sub>1B</sub> receptor knockout mouse has been generated that demonstrates increased aggression and reduced anxiety (Zhuang *et al.*, 1999). Although male 5-HT<sub>1B</sub> KO male mice do not exhibit an AD-like baseline response in the TST, they do show exaggerated increases of 5-HT and augmented behavioral responses to fluoxetine (Knobelman *et al.*, 2001; Mayorga *et al.*, 2001), suggesting an important role for 5-HT<sub>1B</sub> autoreceptors. 5-HT<sub>1B</sub> KO females exhibit a decrease in baseline immobility in the TST and FST compared to KO males and WT mice because of a constitutive disinhibition of 5-HT release (Jones and Lucki, 2005b).

### 5-HT<sub>2A</sub> receptor

Much of the research on 5-HT<sub>2A</sub> receptors has focused on their role in the modulation of dopamine and glutamate release in the medial prefrontal cortex. Antagonists at the receptor have been shown to inhibit dopamine release in the prefrontal cortex (Pehek *et al.*, 2006). Treatment with the 5-HT<sub>2A/2C</sub> receptor agonist DOI causes an increase in glutamate release in the cortex that is blocked by pretreatment with a selective 5-HT<sub>2A</sub> receptor antagonist (Scruggs *et al.*, 2003). Selective 5-HT<sub>2A</sub> receptor antagonists may cause AD-like effects (Table 1) in a number of rodent tests (Albinsson *et al.*, 1994; Patel *et al.*, 2004), and co-administration of 5-HT<sub>2A</sub> receptor antagonists can augment the antidepressant-like effects of SSRIs (Marek *et al.*, 2003, 2005).

### 5-HT<sub>2C</sub> receptor

Treatment with 5-HT<sub>2C</sub> receptor agonists produces AD-like effects (Table 1) in the modified rat FST, resident-intruder social stress model, and OB models of depression (Cryan and Lucki, 2000; Rosenzweig-Lipson *et al.*, 2007). In addition, the selective 5-HT<sub>2C</sub> receptor antagonist SB206533 blocks the behavioral effects of fluoxetine (Cryan and Lucki, 2000). Although the antidepressant mianserin is a 5-HT<sub>2C</sub> receptor antagonist, it produces antidepressant-like effects by blocking  $\alpha_2$  noradrenergic receptors (Cryan and Lucki, 2000). In the mouse FST, the 5-HT<sub>2C</sub> receptor agonist Ro 60-0175 synergized with subactive doses of imipramine, paroxetine, citalopram and fluvoxamine, but antagonized active doses of paroxetine and fluoxetine at higher doses (Clenet *et al.*, 2001). 5-HT<sub>2C</sub> KO mice demonstrate an anxiolytic phenotype with a blunted

CRF response to stress, but their phenotype in depression tests was not reported (Heisler *et al.*, 2007). That 5-HT<sub>2C</sub> KO mice are hyper-responsive to the effects of repeated stress would seem to support the findings that agonists can produce AD-like effects (Chou-Green *et al.*, 2003). On the other hand, some 5-HT<sub>2C</sub> receptor antagonists, including the combined melatonin agonist/5-HT<sub>2C</sub> antagonist agomelatine, have been reported to produce antidepressant-like effects (Bourin *et al.*, 2004; Dekeyne *et al.*, 2008).

### **5-HT<sub>3</sub> receptor**

Antagonists at the 5-HT<sub>3</sub> receptor produce antidepressant-like effects (Table 1) in a number of tests and models (Martin *et al.*, 1992; Mahesh *et al.*, 2007) and co-treatment can augment the effects of sub-threshold doses of SSRIs (Redrobe and Bourin, 1997; Ramamoorthy *et al.*, 2008). On the other hand, 5-HT<sub>3</sub> receptor agonists were shown to attenuate the effects of antidepressant compounds in the rat FST (Nakagawa *et al.*, 1998). The effects of 5-HT<sub>3</sub> receptor antagonists may be due to a direct receptor interaction, because some clinically effective antidepressants have been reported to be functional antagonists at the 5-HT<sub>3</sub> receptor (Eisensamer *et al.*, 2003). Interestingly, female 5-HT<sub>3</sub> receptor KO mice show increased immobility in the FST compared to WT controls, suggesting that there is sex-specific regulation of the receptor (Martin *et al.*, 1992; Bhatnagar *et al.*, 2004; Bravo and Maswood, 2006).

### **5-HT<sub>4</sub> receptor**

5-HT<sub>4</sub> receptor agonists exhibit antidepressant-like effects (Table 1) in rats in a number of tests (FST, OB, and CMS). Most interestingly, 5-HT<sub>4</sub> receptor agonists produce a rapid onset of a number of adaptations seen after chronic AD treatment. Only a 3-day treatment regimen was required to desensitize 5-HT<sub>1</sub> autoreceptors, increase hippocampal neurogenesis, decrease hyperlocomotion in the OB model, and normalize sucrose consumption in the CMS model (Lucas *et al.*, 2007). Pharmacological blockade or genetic deletion of the 5-HT<sub>4</sub> receptor appears to exert anxiolytic effects (Smriga and Torii, 2003; Compan *et al.*, 2004; Conductier *et al.*, 2006).

### **5-HT<sub>6</sub> receptor**

Research has shown that similar effects are seen after treatment with both agonists and antagonists (Table 1). Both sets of compounds produce antidepressant-like

and anxiolytic effects in a number of rodent tests (Svenningsson *et al.*, 2007; Wesolowska and Nikiforuk, 2007; Wesolowska *et al.*, 2007). There is also evidence that the effects of 5-HT<sub>6</sub> receptor agonists may involve modulation of GABAergic neurotransmission (Schechter *et al.*, 2008).

### **5-HT<sub>7</sub> receptor**

Genetic deletion and treatment with 5-HT<sub>7</sub> receptor antagonists produce AD-like effects (Table 1) in the FST and TST (Guscott *et al.*, 2005; Hedlund *et al.*, 2005; Wesolowska *et al.*, 2006). Research also suggests that 5-HT<sub>7</sub> receptor antagonists have potential as adjunct AD treatments. A recent study showed that 5-HT<sub>7</sub> receptor antagonists increased the effects of citalopram on TST (mice) and REM sleep (rats) (Bonaventure *et al.*, 2007).

### **5-HT transporter (SERT) KO mice**

The depression-related behavior of SERT KO mice appears to be affected by the background strain used to create the mouse. With a C57/BL6 background, there are no differences in baseline behavior (Table 1) in the FST or TST between KO and wild-type (WT) mice (Holmes *et al.*, 2002). However, on the 129S6 background, SERT KO mice exhibit an increase in immobility in the FST (pro-depressive) and a decrease in immobility in the TST (AD-like) response at baseline compared to WT controls (Holmes *et al.*, 2002; Lira *et al.*, 2003). On the C57/BL6 background, fluoxetine has no effect on behavior in the TST, while antidepressants that are not dependent on 5-HT to exert their effects (desipramine and imipramine) are still effective (Holmes *et al.*, 2002). It is unclear why deletion of the SERT protein does not produce the same behavioral effects as pharmacological blockade of the protein with SSRIs, but possible explanations include the developmental alteration of 5-HT receptor function and/or changes in the endogenous release of 5-HT (Fabre *et al.*, 2000; Gobbi *et al.*, 2001).

## **Conclusion**

A large amount of research has elucidated the role of the 5-HT system in genetic and molecular mechanisms underlying the pathology and treatment of depression. Instead of focusing on one component of 5-HT transmission as the source for depression vulnerability, the current concept identifies different 5-HT genes and pathways as a family of risk factors that can contribute to the pathology

of depression (Jans *et al.*, 2007). The genetic models of the deletion of TPH and 5-HT receptors emphasizes the critical role of 5-HT during development for the life-long expression of normal affective behaviors. Although genetic deletion of individual 5-HT receptors has not yet reliably reproduced a depressive behavioral phenotype, the genetic deletion of TPH may reproduce a depressive-like behavioral phenotype.

Behavioral and neuropharmacology studies have attempted to identify the 5-HT receptors associated with the therapeutic effects of SSRIs. Identifying the 5-HT receptors that support the therapeutic effects of SSRIs may lead to the development of more effective antidepressant drugs with fewer side effects. However, the present findings indicate that multiple 5-HT receptors are likely to participate in antidepressant responses, and it is unclear that the entire antidepressant effect of SSRIs can be recapitulated by a selective 5-HT receptor agonist or antagonist. However, many of the 5-HT receptors have been discovered only recently. Therefore, selective agonists and antagonists have not yet been synthesized, and specific investigation of the effects mediated by these receptors has not been fully possible. Undoubtedly, behavioral testing in animals, particularly utilizing the models outlined in this chapter, will play an important role in the further exploration of the relationship between the 5-HT system and depression.

**Abstract:** Drug addiction is a major psychiatric disease with, currently, no truly effective treatment available. Drug addiction involves many different behaviors. Given the involvement of serotonin (5-HT) in virtually all behaviors and brain plasticity at cellular, molecular and systems levels, one can readily assume a 5-HT contribution to the establishment and maintenance of addiction-related behaviors and their neuronal mechanisms. In this chapter we review the role of the 5-HT system in addiction-related behaviors for major addictive drugs, such as cocaine, amphetamine, methamphetamine, MDMA (ecstasy), morphine, heroin and nicotine. We discuss the impact of these drugs on 5-HT activity, and how this activity might translate into behavior by activating 5-HT receptors. The effects of serotonergic manipulations on addiction-related behaviors in animal models and in human therapy of addiction are reviewed. Intensive research has shown that drug-induced 5-HT activation does not have a uniform 'proactive effect' (i.e., neurochemical activity that triggers behavioral activation) on addiction-related behavior, but might often serve a 'counteractive function', thus limiting the expression of behavior which is driven by other neurochemical effects of the drug. 5-HT receptors can have very different effects on addiction-related behaviors depending on their localization in the brain, the cell type, and the synapse. Some receptor populations do appear to have proactive effects – i.e., translate the drug-induced 5-HT increase into addiction-related behaviors – while others counteract them, or are not involved. While acknowledging this complexity will be important for an understanding of the 5-HT role in drug addiction, it also provides a challenge to the use of 5-HT system components for therapy in humans.

**Keywords:** serotonin, addiction, animal models, clinical trials, cocaine, amphetamine, methamphetamine, MDMA, morphine, nicotine.

## Introduction

Drug addiction in humans is a serious and complex psychiatric disease (*DSM-IV*, American Psychiatric Association, 1994), which not only affects the individual user but all aspects of social and economic life. Even after decades of intensive research in drug addiction, there is still only a limited understanding of the brain mechanisms involved. This is most obviously reflected in the lack of effective behavioral and/or pharmacotherapies for addiction. The quest to understand the development of drug abuse habits and drug addiction, therefore, is still a major challenge for behavioral neuroscience. Drug addiction involves different behaviors, which are in competition with non-drug-related behaviors. Most of the drug-related behaviors do

not establish a new class of behavioral plasticity, but are essentially modifications of normal (i.e., non-drug-related) behaviors. They involve, for example, instrumental and Pavlovian conditioning. Accordingly, an understanding of the brain mechanisms of addiction would necessarily need to co-evolve with an understanding of how natural behavioral plasticity is mediated in the brain.

Addiction was seen as a malfunction of the brain's hedonic tone regulation (Wise, 1980, 2002), and later as malfunction of the motivational systems (Koob, 1992; Robinson and Berridge, 1993, 2003; Di Chiara, 1995) in that these systems were 'hijacked' by intense pharmacological reinforcers. While there are still problems to characterize brain mechanisms serving the psychological concepts of hedonia and motivation, it proved to be more successful to characterize mechanisms of reinforcement learning (Robbins and Everitt, 1996; Kelley and Berridge, 2002). With this background information, it is easier to

\* Corresponding author  
E-mail: christian.muller@kcl.ac.uk

understand drug effects within these systems and to view addiction as a disturbance of the brain reinforcement systems (Kalivas and Volkow, 2005; Koob and Le, 2008). However, reinforcement learning is just one type of learning and memory, leaving a number of important addiction-related behaviors out of the concept. This issue was better addressed when evidence accumulated that drugs of addiction cause molecular effects and structural and functional changes to the brain that are comparable with those of normal learning (Robinson and Kolb, 2004). Furthermore, when drugs induced this plasticity, it prevented normal stimulation and behavior from inducing it (Kolb *et al.*, 2003). In turn, natural stimuli (such as environmental enrichment and induced exploration behavior) were able to compete with reinstatement of drug-related behavior (Solinas *et al.*, 2008). These findings might highlight the competitive character of drug-related behaviors with non-drug-related behaviors. An alternate view on drug addiction is to look at it as a disturbance of the brain's memory systems (Nestler, 2002; Kelley, 2004; Hyman *et al.*, 2006). This conceptualization allows an incorporation of the previous models of hedonic, motivational and reinforcement learning into a broader view.

Serotonin (5-HT) was shown to be of essential importance not only to maintain synaptic plasticity throughout the whole lifespan (see Chapter 3.2), for the hedonic tone (see Chapter 4.13), in motivational processes (see Chapter 3.3) and in reinforcement processes (see Chapter 3.7), but also for learning and memory (see Chapter 3.9). Accordingly, it is not surprising that drugs of addiction, which induce profound changes in extracellular 5-HT activity and 5-HT receptor function, change the behavior-organizing circuitry of the brain either directly, by modulating the 5-HT system, or indirectly, by 5-HT effects on other transmitter systems (see Chapter 2.8). In this chapter we review the action of major addictive drugs, such as cocaine, amphetamine, methamphetamine, 3,4-methylenedioxymethamphetamine (MDMA, ecstasy), heroin, morphine and nicotine, on the 5-HT system, and how components of the 5-HT system contribute to the establishment and expression of addiction-related behaviors (for the role of 5-HT in alcohol addiction: see Chapter 3.7). We describe the influence of increased and decreased 5-HT activity on addiction-related behavior in animal models. It should be noted that drugs of addiction usually have many more effects on brain function and behavior than those related to addiction in general (see, for example, Kalivas, 2005; Müller *et al.*, 2007a); this, however, will not be discussed here. A major part of the chapter will focus on the contribution of single 5-HT receptor subtypes. In addition, we discuss how components of the 5-HT system have been tested as potential targets for a pharmacotherapy of drug addiction in human patients.

## Measuring drug addiction in animal models

Many drugs of addiction evoke at low to medium doses, and parallel to pleasant feelings, an increase in locomotor activity. Acute hyperlocomotor effects, although not directly recognized as a harmful addiction-related behavior in humans and animals, are often investigated as a crude indicator for the subjective effects of the drug.

Due to the brain's function to maintain homeostasis, counter-regulatory processes are evoked by the strong neurochemical impact of a psychostimulant drug (Solomon, 1980; Koob and Le, 2008). Immediately after the intake of a psychostimulant drug, functional changes in the brain occur that may endure beyond the presence of the actual drug/metabolites in the brain (see, for example, Ungless *et al.*, 2001). These functional changes and corresponding homeostatic responses may be responsible for behavioral and subjective effects of the drug intake that outlast the presence of the drug in the brain. These effects, believed to be neuronal adaptations, are also the basis for asensitization of the acute hyperlocomotor effects – i.e., when the same dose of the drug has increasing effects after only few administrations (Vanderschuren and Kalivas, 2000).

When the consumption of a drug is repeated, the frequency of intake may increase, and eventually a transition to a binge-taking pattern can take place (Kramer *et al.*, 1967; Gawin, 1991). This transition occurs because the euphoric effects of the drug develop tolerance – i.e., the same dose of a drug induces less euphoria with repeated administration. At this point, not only do the acute effects of the intake change, but gross behavioral changes may also appear. These new behaviors are related to drug-seeking and the self-administration of the drug. This behavioral pattern occurs despite the possible development of severe negative consequences of the drug consumption (Deroche Gamonet *et al.*, 2004; Vanderschuren and Everitt, 2004). The occurrence and frequency of such newly established behaviors is usually considered when drug use, abuse or addiction is diagnosed. Chronic drug use induces neuroadaptive changes, the behavioral manifestations of which can often be observed in the absence of the drug. In this case, drug-related behaviors are initiated in a drug-free state. The mechanisms behind these effects are not neurochemical rebound responses, but are based on morphological and functional long-term changes in the brain (Robinson and Kolb, 2004). Accordingly, brain substrates mediating the acute pharmacological drug effects on behavior are not necessarily the same as those underlying addiction-related behaviors in a drug-free state. Since the addiction-related behaviors promote continued drug taking, the resulting long-term neurophysiological alterations in brain function continue to be

reinforced by the acute neuropharmacological effects of the drug.

In this chapter, we focus on the major paradigms to measure drug addiction-related behaviors in animal models. Basic experiments measure the effects of serotonergic manipulations on the acute drug-induced locomotor activity. When drugs are administered repeatedly, the acute behavioral effects can sensitize. Regarding the role of 5-HT in the sensitization of the hyperlocomotor effects, induction and expression of sensitization can be distinguished and independently modulated by various treatments. The discriminative stimulus effects of addictive drugs in animals serve as a model for the subjective drug effects in humans. In animal studies, discriminative stimulus properties are usually assessed by pairing a drug cue with the availability of a food or water reward when pressing one of two levers. If a certain drug can be readily differentiated from saline, responding takes place on the rewarded lever. This paradigm allows testing of the prerequisites for drug discrimination in the brain. It also investigates the ability of a pharmacological treatment to substitute for the drug as a pharmacological cue.

Chronic treatment with addictive drugs leads to the development of various addiction-related behaviors that are expressed in an undrugged state. When the effects of a pharmacological treatment are repeatedly paired with a certain place context (or cues), and in a free choice this place is preferred over another, originally equally preferred place, a conditioned place preference (CPP) is inferred. If the paired place is avoided in the test, a conditioned place aversion (CPA) is concluded (Bardo and Bevins, 2000; Tzschentke, 2007).

Self-administration of a drug is probably the most informative test for addiction related behaviors in animals (Spealman and Goldberg, 1978). In this paradigm, animals learn to perform an operant response to receive the drug, or a sensory stimulus (secondary reinforcer) which was previously associated with the delivery of the drug. Animals work to obtain both stimuli that are associated with the drug (conditioned reinforcers), as well the drug itself. The motivation to self-administer addictive drugs can be measured in fixed-ratio and progressive-ratio schedules of reinforcement. The response level at which the animal ceases to respond (the breakpoint) in a progressive-ratio schedule of reinforcement is an indicator of the motivational level (Depoortere *et al.*, 1993; Richardson and Roberts, 1996; Roberts *et al.*, 2002). If the behavioral activity that led to drug administration is no longer followed by the drug, the behavior undergoes extinction. Extinguished self-administration behavior can, however, be reinstated by stress, by cues signaling the availability of the drug, or by application of the drug itself (De Wit and Stewart, 1981; Shaham *et al.*, 2003).

Of increasing importance in addiction research is the question of whether a pharmacological treatment can prevent the reinstatement of previously extinguished drug-seeking behavior.

When the well-established self-administration of certain drugs is abruptly discontinued in humans, a severe withdrawal syndrome, characterized by dysphoria, anhedonia depression, anxiety and psychomotor alterations, is observed. While dysphoria and depression may disappear after a few days, a sensitized hyperlocomotor response and sensitized behavioral stereotypies may still be observed after years of abstinence (Kramer *et al.*, 1967; Gawin, 1991). To target the aversive effects of withdrawal is an important component of a potential treatment strategy for drug addiction. The 5-HT system has been investigated for its role in the increased reward threshold during withdrawal, using intracranial self-stimulation (ICSS). In the ICSS paradigm, animals learn to perform an operant task reinforced by electrical stimulation of, for example, the lateral hypothalamus (Olds and Milner, 1954; Markou and Koob, 1992). An increase in the stimulation threshold that is required to maintain the ICSS behavior indicates a reduced reward value of the electrical stimulation, and may be seen as a reduced hedonic tone in the brain. For detailed reviews on the advantages and shortcomings of each animal model of drug addiction, see Sanchis-Segura and Spanagel (2006) and Olmstead (2006).

## Cocaine

### *The effects of cocaine on 5-HT activity*

Cocaine, a major alkaloid of the South American shrub *Erythroxylum coca*, is a powerful pharmacological reinforcer with a highly judged abuse potential (Gawin, 1991; Nutt *et al.*, 2007). A great number of studies reported increased extracellular 5-HT levels after acute cocaine administration. In the rat, acute cocaine administration leads to a temporally limited increase in extracellular 5-HT levels in various subcortical structures, such as the nucleus accumbens (Nac) (Broderick *et al.*, 1993; Parsons and Justice, 1993; Teneud *et al.*, 1996; Andrews and Lucki, 2001; Müller *et al.*, 2002a), dorsal striatum (Bradberry *et al.*, 1993), ventral pallidum (Sizemore *et al.*, 2000), hippocampus (Müller *et al.*, 2002a, 2004a), thalamus (Rutter *et al.*, 1998), hypothalamus (Shimizu *et al.*, 1992), ventral tegmental area (VTA) (Parsons and Justice, 1993; Chen and Reith, 1994; Reith *et al.*, 1997) and dorsal raphe nucleus (DRN) (Parsons and Justice, 1993). Cocaine also increased extracellular 5-HT levels in various neocortical areas, such as the prefrontal

cortex (PFC) (Mangiavacchi *et al.*, 2001; Pum *et al.*, 2007), the occipital and temporal cortices (Müller *et al.*, 2007b), and the entorhinal and perirhinal cortices (Pum *et al.*, 2007, Figure 1). Small doses of cocaine, which had little effect on, for example, locomotor activity, led to a much more intense and prolonged increase in 5-HT than sensory stimulation (Müller *et al.*, 2007b; Pum *et al.*, 2007, 2008) or behavioral activity (Rueter *et al.*, 1997). When animals are allowed to self-administer cocaine with an unlimited access, 5-HT levels increase in the Nac and ventral pallidum, and then remain at a plateau (Parsons *et al.*, 1995; Sizemore *et al.*, 2000), possibly self-titrated by the self-administration behavior. The profound cocaine effects on extracellular 5-HT levels, which have occurred in virtually all brain areas that have been investigated so far, show a similar time-course to many acute behavioral and subjective effects, suggesting that 5-HT might contribute to, or at least modulate, the effects of cocaine.

When access to cocaine is stopped after prolonged drug self-administration, a withdrawal syndrome commences. This is characterized by dysphoria, anhedonia, depression and anxiety in humans. These behavioral effects appear to be associated with profound changes in 5-HT activity in rodents. It has been reported that extracellular 5-HT levels in the Nac and ventral pallidum, which were increased during cocaine self-administration, drop to below pre-drug baseline levels within 2 hours of withdrawal (Parsons *et al.*, 1995; Sizemore *et al.*, 2000). This reduction in 5-HT activity in the Nac could be observed for at least 12 hours (Parsons *et al.*, 1995). When cocaine was administered by the experimenter on 10 consecutive days, no change in basal 5-HT levels was found in the Nac, the VTA or the DRN 1 day after this treatment regimen in rats (Parsons and Justice, 1993). However, the chronic treatment led to a significantly higher percentage 5-HT increase after an acute cocaine challenge in all three areas, suggesting an augmented responsiveness of the 5-HT system after chronic cocaine treatment (Parsons and Justice, 1993). Given the similarities in the behavioral state between psychostimulant withdrawal and depression, it can be argued that reduced 5-HT activity in the limbic system may be a common neurochemical mechanism (Parsons *et al.*, 1995; Baumann and Rothman, 1998; Markou *et al.*, 1998).

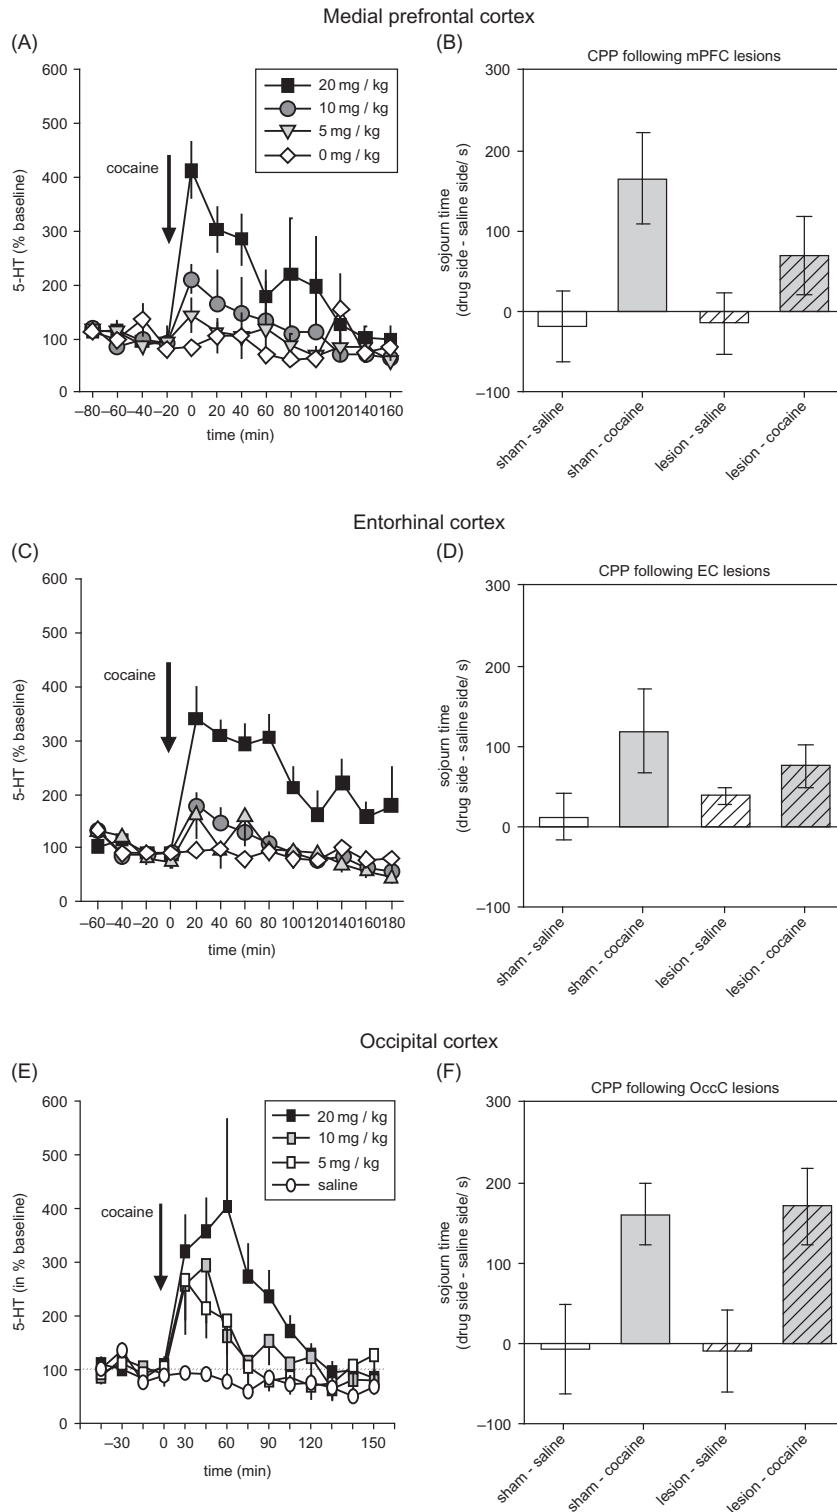

### ***Reducing and potentiating 5-HT activity***

Studies on the role of the 5-HT system in cocaine's behavioral effects used selective neurotoxins to lesion the 5-HT neurons, or used tryptophan hydroxylase inhibitors to reduce 5-HT synthesis. Scheel-Krüger and colleagues (1977) used p-chlorophenylalanine (pCPA) as a 5-HT synthesis inhibitor in rats. They found that cocaine-induced

hyperlocomotion was potentiated in rats after pCPA pretreatment. This finding was confirmed later by Svingos and Hitzemann (1992) and Herges and Taylor (1998) for several doses of cocaine. Also, potentiation of cocaine-induced hyperlocomotion was reported by Morrow and Roth (1996), who used 5,7-dihydroxytryptamine (5,7-DHT) to lesion serotonergic neurons. Local lesion studies, however, showed significant regional differences in the contribution of 5-HT to cocaine-induced hyperactivity. A local lesion of the mPFC with 5,7-DHT attenuated the hyperlocomotor effects of cocaine, while 5-HT depletion of the entorhinal or occipital cortices had no effect (Pum *et al.*, 2008). Together, several treatments that reduced the availability of 5-HT in the brain suggest an inhibitory role of the 5-HT system in cocaine-induced hyperlocomotion, with, however, regional differences in the brain. This view is further supported by studies that increased the availability of 5-HT in the brain by applying a 5-HT precursor, a selective serotonin reuptake inhibitor (SSRI) or a 5-HT releaser. In an early study, Pradhan *et al.* (1978) injected rats with 5-hydroxytryptophan, the direct 5-HT precursor, and found an attenuated locomotor response after cocaine. Molina and colleagues (2001) used L-tryptophan, the amino acid precursor of 5-HT, to increase 5-HT availability. They also reported a diminished locomotor response to cocaine afterwards. However, a potentiated locomotor response to cocaine was reported after the SSRIs fluoxetine and fluvoxamine (Herges and Taylor, 1998; Bubar *et al.*, 2003), but not after citalopram or sertraline (Fletcher *et al.*, 2004a). Interestingly, the fluoxetine-enhancing effects were also seen in animals with a 5,7-DHT-induced 5-HT depletion, which suggested the involvement of non-serotonergic effects of fluoxetine (Fletcher *et al.*, 2004a).

The SSRIs fluoxetine and citalopram did not substitute for cocaine in discriminative stimulus testing in rats. However, several SSRIs were shown to enhance the effects of, in particular, a sub-threshold dose of cocaine, resulting in a leftward shift of the dose-response curve in rats (Baker *et al.*, 1993; Callahan and Cunningham, 1997; Kleven and Koek, 1998; Klein and Gulley, 2009). In monkeys, in contrast, the SSRIs citalopram and fluoxetine attenuated the discriminative stimulus effects of cocaine (Spealman, 1993).

Cocaine induces a profound CPP in rats and mice (Tzschentke, 2007). A recent study in rats investigated the role of 5-HT in various cortical areas that showed an increase in the 5-HT response after acute cocaine treatment (Pum *et al.*, 2007; see also Figure 1). A depletion of 5-HT in the medial PFC (mPFC) by 90 percent and in entorhinal cortex by 61 percent significantly attenuated cocaine-induced CPP. In contrast, 78 percent depletion in the occipital cortex had no effect on CPP. This suggests multiple dissociations in the functional role of 5-HT in

**Figure 1** Acute effects of cocaine on extracellular serotonin (5-HT) levels in the medial prefrontal (A), entorhinal (C), and occipital cortex (E). Results are expressed as percent (mean  $\pm$  SEM) of the four pre-stimulus samples (baseline) set as 100%. Place preference scores (time spent in conditioning compartment – time spent in pseudo-conditioning compartment; mean  $\pm$  SEM) of rats with 5,7-DHT- or sham-lesions of the medial prefrontal (B), entorhinal (D), and occipital cortex (F). Figures modified from Müller *et al.* (2007a), with permission from Elsevier; and from Pum *et al.* (2007, 2008), with kind permission from Springer Science.

the cortex in cocaine-induced CPP and hyperlocomotor effects.

Global as well as forebrain- or amygdala-restricted 5-HT lesions, using 5,7-DHT, increased responding for cocaine in a progressive ratio schedule in rats (Loh and Roberts, 1990). A more complex role of 5-HT was suggested in studies by Tran-Nguyen *et al.* (1999, 2001), showing that global 5-HT reductions, using either pCPA or 5,7-DHT, attenuated cocaine-seeking during extinction of responding for cocaine, but increased the effectiveness of a cocaine priming injection in reinstating drug-seeking behavior. Complementary to this, the SSRI fluoxetine reduced the self-administration of low doses of cocaine in rats, but did not affect it at higher doses (Porrino *et al.*, 1989; Peltier and Schenk, 1993). Alaproclate, however, decreased responding for cocaine in a second-order schedule of drug delivery in squirrel monkeys (Czoty *et al.*, 2002). Pre-treatment with the 5-HT precursor L-tryptophan decreased the breakpoints in a progressive ratio schedule of intravenous cocaine self-administration in rats (McGregor *et al.*, 1993).

Inhibitory effects of 5-HT on the motivational/reinforcing effect of cocaine were confirmed in genetic approaches using either serotonin transporter (SERT) knockout (KO) mice or target-selected ENU-induced mutagenesis of the SERT in rats. SERT KO mice and rats showed an enhanced cocaine-induced CPP (Sora *et al.*, 2001; Homberg *et al.*, 2008). For the rats (Homberg *et al.*, 2008), but not for the mice (Thomsen *et al.*, 2009), enhanced cocaine self-administration was also reported. This would be largely in line with the studies showing that 5-HT activation exerts a rather inhibitory influence on major addiction-related behaviors.

### 5-HT receptors

#### 5-HT<sub>1A</sub> receptor

A prominent, acute behavioral effect of psychostimulant drugs is an increase in locomotor activity at low to medium doses (e.g. Segal, 1975; Scheel-Krüger *et al.*, 1977; Miczek and Yoshimura, 1982). The hyperlocomotor response was shown to have a similar time course as the acute subjective effects and coincides with many neurochemical effects. A considerable number of studies have investigated the contribution of 5-HT<sub>1A</sub> receptors in the brain to the hyperlocomotor effects of cocaine. The hyperlocomotor effects of a low dose of cocaine (5 mg/kg) were blocked by pre-treatment with the 5-HT<sub>1A</sub> receptor agonist 8-OH-DPAT in rats (Przegalinski and Filip, 1997). Also, the partial 5-HT<sub>1A</sub> receptor agonist, S 16924, and the full agonist, osetozotan, blocked cocaine-induced hyperlocomotion in rats and mice (Millan *et al.*,

1998; Nakamura *et al.*, 2006). Other studies, in contrast, found that stimulation of the 5-HT<sub>1A</sub> receptor with 8-OH-DPAT potentiated cocaine-induced hyperlocomotion (De La Garza and Cunningham, 2000; Carey *et al.*, 2001, 2002, 2004a; Müller *et al.*, 2003). Since the effects of 8-OH-DPAT alone on locomotor activity depend on experimental parameters, such as the size of the arena, pre-test handling, and habituation procedures, which interfere with the emotional status of the animals, it may not be surprising that 5-HT<sub>1A</sub>-receptor effects on cocaine-induced hyperlocomotion depend on these factors. The 5-HT<sub>1A</sub> receptor antagonist, NAN-190, blocked cocaine-induced behavioral activity in rats (King *et al.*, 1993). The selective 5-HT<sub>1A</sub> receptor antagonist, WAY 100135, however, failed to affect small dose cocaine-induced hyperlocomotion (Przegalinski and Filip, 1997), while the selective and silent 5-HT<sub>1A</sub> receptor antagonist, WAY 100635, clearly attenuated the acute hyperlocomotor effects of cocaine in rats (Carey *et al.*, 2000, 2001, 2002; Müller *et al.*, 2002a, b). In mice, however, pre-treatment with WAY 100635 potentiated cocaine-induced hyperlocomotion (Nakamura *et al.*, 2006) or had no effect (Herges and Taylor (1998) when administered 1 hour before cocaine.

In order to determine the contribution of different local 5-HT<sub>1A</sub> receptor populations to the behavioral effects of psychostimulants, two different approaches have been used: (1) local application studies targeting 5-HT<sub>1A</sub> receptors in restricted brain areas, and (2) systemic application studies with very low doses of 5-HT<sub>1A</sub> receptor agonists or antagonists, which preferentially target the more sensitive 5-HT<sub>1A</sub> autoreceptors in the raphe nuclei. In the systemic approach with low doses it was shown that 8-OH-DPAT, which preferentially stimulate 5-HT<sub>1A</sub> autoreceptors, blocked the acute hyperlocomotor effects of cocaine (Carey *et al.*, 2004a, b, 2005a). Interestingly, the acute inhibitory effect of a low dose of 8-OH-DPAT was reversed by repeated treatment over 9 days (Carey *et al.*, 2005a); this was caused by a transformation of the 8-OH-DPAT drug cue into a cocaine-conditioned stimulus, which by itself elicits hyperlocomotor activity (Carey *et al.*, 2005b, c). Pre-treatment with the 5-HT<sub>1A</sub> receptor antagonist WAY 100635 at a low dose blocked the acute hyperlocomotor effects of cocaine (Carey *et al.*, 2004b). The studies using local application also mainly support an inhibitory role of 5-HT<sub>1A</sub> autoreceptors in cocaine-induced hyperlocomotion, but also showed that there are differences in the contribution of several 5-HT<sub>1A</sub> autoreceptor populations. Activating 5-HT<sub>1A</sub> autoreceptors in the median raphe nucleus (MRN) by local application of 8-OH-DPAT or blocking them with WAY 100635 did not affect cocaine-induced hyperlocomotion (Herges and Taylor, 1999; Szumlinski *et al.*, 2004). In contrast,

the activation of 5-HT<sub>1A</sub> autoreceptors in the DRN by 8-OH-DPAT potentiated cocaine-induced hyperlocomotion (Szumlinski *et al.*, 2004), suggesting a facilitatory role for these receptors. The application of WAY100635 into the DRN potentiated cocaine-induced hyperlocomotion (Herges and Taylor, 1999). Local application studies have also revealed multiple dissociations in the contribution of the several postsynaptic 5-HT<sub>1A</sub> receptor subpopulations to the hyperlocomotor effects of cocaine. Application of 8-OH-DPAT into the ventral hippocampus of rats showed that local 5-HT<sub>1A</sub> receptors suppress cocaine-induced hyperlocomotion (Müller *et al.*, 2004a), while application of 8-OH-DPAT into the ventral striatal region potentiated cocaine-induced hyperlocomotion (Müller *et al.*, 2004b). Overall, the available studies support the view that 5-HT<sub>1A</sub> receptors are essentially involved in acute cocaine-induced hyperlocomotion. However, it appears that 5-HT<sub>1A</sub> autoreceptors and postsynaptic 5-HT<sub>1A</sub> receptors contribute differently (for review, see Müller and Huston, 2006; Müller *et al.*, 2007a).

A sensitization of the acute hyperlocomotor effects of cocaine can be observed after only a few days of repeated treatment (see, for example, Shuster *et al.*, 1977; Kalivas *et al.*, 1988; Yeh and Haertzen, 1991; Camp *et al.*, 1994). The induction of sensitization for the hyperlocomotor effects of cocaine was potentiated by 8-OH-DPAT in rats (De La Garza and Cunningham, 2000; Carey *et al.*, 2001), while it was attenuated by antagonism of the 5-HT<sub>1A</sub> receptor with WAY 100635 (Carey *et al.*, 2001). Furthermore, the expression of cocaine-induced locomotor sensitization was attenuated by the 5-HT<sub>1A</sub> receptor antagonist NAN-190 (King *et al.*, 1993). In mice, however, the 5-HT<sub>1A</sub> receptor agonist osetozotan blocked the establishment and expression, but not the maintenance, of cocaine-induced sensitization (Ago *et al.*, 2006b). The majority of the findings suggest a facilitatory role of 5-HT<sub>1A</sub> receptors in the induction and expression of cocaine-induced sensitization, but no role in its maintenance.

Preferentially stimulating 5-HT<sub>1A</sub> autoreceptors with the systemic application of low doses of 8-OH-DPAT (0.05 mg/kg, i.p.) initially blocked the acute hyperlocomotor effects of cocaine, but facilitated the induction of locomotor sensitization during repeated cocaine treatment (Carey *et al.*, 2005a). This effect, however, appeared not to be a true sensitization effect, but rather an 8-OH-DPAT drug-cue conditioned stimulus effect (Carey *et al.*, 2005b). A local application study targeted 5-HT<sub>1A</sub> autoreceptors in the DRN and MRN with 8-OH-DPAT. 5-HT<sub>1A</sub> receptors were found to have a facilitatory role in the MRN, but not in the DRN, in the induction of cocaine-induced locomotor sensitization (Szumlinski *et al.*, 2004). This finding supports the view that there are not only dissociable

contributions of 5-HT<sub>1A</sub> autoreceptors and postsynaptic receptors, but also dissociations within the population of the 5-HT<sub>1A</sub> autoreceptors, with a dominant role for the MRN (Müller and Huston, 2006).

Cocaine can be discriminated from saline by several species. However, stimulation of 5-HT<sub>1A</sub> receptors with 8-OH-DPAT, or the partial agonists buspirone and gepirone, does not substitute for cocaine in rats (Callahan and Cunningham, 1997). The discriminative stimulus properties of cocaine were also not modulated by medium doses of the partial 5-HT<sub>1A</sub> receptor agonist buspirone, or the full agonist 8-OH-DPAT, in rats (Rapoza, 1993; Callahan and Cunningham, 1995, 1997; Przegalski and Filip, 1997; Kleven and Koek, 1998). Buspirone and 8-OH-DPAT nevertheless reduced the discriminative stimulus properties of cocaine when administered at higher doses. At these doses, both agonists also suppressed general responding (Rapoza, 1993; Callahan and Cunningham, 1995, 1997), which suggests rather unspecific effects. The authors explained this finding, in part, by the prominent actions of buspirone, but not gepirone, at the D2 dopamine (DA) receptor (Van Wijngaarden *et al.*, 1990), which was shown to block the discriminative stimulus properties of the D2 DA receptor agonist apomorphine in rats and monkeys (Kamien and Woolverton, 1990; Rijnders and Slangen, 1993). A study in pigeons reported a partial substitution for cocaine by 8-OH-DPAT in two of four animals tested, and a partial blockade of the discriminative stimulus effects of cocaine by the 5-HT<sub>1A</sub> receptor antagonist NAN-190 (Johanson and Barrett, 1993). Since only four animals were tested in this study and statistical results are somewhat unclear, conclusions must be limited. The 5-HT<sub>1A</sub> receptor antagonist NAN-190 neither substituted for cocaine nor altered its discriminative stimulus properties in rats (Callahan and Cunningham, 1995). The local application of 8-OH-DPAT into the VTA or SN neither substituted for cocaine nor modulated its discriminative stimulus properties (De La Garza *et al.*, 1998). Altogether, most studies show that 5-HT<sub>1A</sub> receptor agonists do not substitute for cocaine, and 5-HT<sub>1A</sub> receptor antagonists do not modulate the discriminative stimulus properties. From these findings, it may be concluded that 5-HT<sub>1A</sub> receptors do not play a major role in the discriminative stimulus properties of cocaine.

Cocaine induces a profound CPP in rodents (Spyraki *et al.*, 1987; Durazzo *et al.*, 1994; Bardo and Bevins, 2000; Tzschentke, 2007). The 5-HT<sub>1A</sub> receptor agonist 8-OH-DPAT facilitates the expression of cocaine-induced CPP in mice (Ali and Kelly, 1996). However, the partial 5-HT<sub>1A</sub> receptor agonist buspirone did not modify the establishment, as well as the expression, of cocaine-induced CPP (Ali and Kelly, 1997; Ettenberg and Bernardi, 2007). Nevertheless, evidence suggests that buspirone can

attenuate the delayed aversive effects of cocaine resulting in CPA (Ettenberg and Bernardi, 2007). Although not much is known about the role of 5-HT<sub>1A</sub> receptors in the establishment and expression of cocaine-induced CPP, the available data suggest no contribution to the establishment, but a possible facilitatory role in CPP expression and in subsequent aversive effects.

Several studies have shown drug-seeking and self-administration of cocaine in rodents (e.g., Arroyo *et al.*, 1998), dogs (Risner and Jones, 1980) and monkeys (e.g., Johanson *et al.*, 1976; Bedford *et al.*, 1980; Ritz and Kuhar, 1989) under different schedules of reinforcement. An inverted U-shaped dose-response function was established for infusion of cocaine under fixed-ratio schedules (Spealman, 1993; Arroyo *et al.*, 1998). Under a progressive-ratio schedule, the self-administered amount of cocaine increases with the dose of cocaine obtained in each infusion (Depoortere *et al.*, 1993). Peltier and Schenk (1993) reported a decrease in cocaine self-administration after pre-treatment with the 5-HT<sub>1A</sub> receptor agonist 8-OH-DPAT. Homberg *et al.* (2004) investigated the effects of 8-OH-DPAT and buspirone on cocaine self-administration in a progressive-ratio and a fixed-ratio schedule of reinforcement. In the progressive-ratio schedule, 8-OH-DPAT increased absolute responding for cocaine, while it significantly reduced responding in a fixed-ratio schedule. Buspirone, in contrast, partially reduced responding for cocaine in a progressive-ratio schedule, but enhanced it in a fixed-ratio schedule. The authors interpreted their findings as a preferential decrease in cocaine self-administration by 5-HT<sub>1A</sub> receptor activation (Homberg *et al.*, 2004). This interpretation was supported by findings in mice showing an inhibitory effect of 8-OH-DPAT (0.3 mg/kg) in a progressive-ratio schedule of cocaine self-administration (Parsons *et al.*, 1998). One study investigated the effects of the 5-HT<sub>1A</sub> receptor agonist ipsapirone on oral cocaine self-administration in rats. In that study, cocaine and ipsapirone were mixed in the drinking fluid with unrestricted access. The study, however, did not find an effect of ipsapirone on voluntary oral cocaine consumption (Mosner *et al.*, 1997). Several studies investigated the effects of 5-HT<sub>1A</sub> receptor agonists on cocaine self-administration in non-human primates. Gold and Balster (1992) compared the effects of the two partial 5-HT<sub>1A</sub> receptor agonists buspirone and gepirone on the self-administration of cocaine in a fixed-ratio schedule in rhesus monkeys. At medium doses, buspirone increased self-administration of cocaine; at the highest dose of buspirone, a significant decrease was observed. Gepirone did not affect self-administration of cocaine at any dose tested. The highest doses of both drugs also disrupted the consumption of food. When buspirone and gepirone

administration was repeated over 10 days, no effect on the self-administration of cocaine was evident (Gold and Balster, 1992). Since buspirone has a much higher affinity to D2 dopamine (DA) receptors than gepirone (Van Wijnngaarden *et al.*, 1990), the effects of buspirone on the self-administration of cocaine may have been mediated by a dopaminergic mechanism (Gold and Balster, 1992). A study in cynomolgus monkeys, where animals could respond for different doses of cocaine or food in a fixed-ratio schedule of reinforcement, found that 8-OH-DPAT increased the choice of cocaine over food, but only when a low dose of cocaine was tested, which was originally not preferred over food. In this condition, 8-OH-DPAT seemed to increase the reinforcing strength of cocaine. At cocaine doses which were originally preferred to the food, 8-OH-DPAT pre-treatment did not modify responding (Czoty *et al.*, 2005). Also, 5-HT<sub>1A</sub> receptor KO mice have been tested regarding cocaine-induced behavior. These mice acquired cocaine self-administration in the same rate as their wild-type littermates, and showed the same regular within-session responding (Rocha *et al.*, 1998). In summary, the majority of studies in rodents and monkeys suggest that activation of 5-HT<sub>1A</sub> receptors attenuates the self-administration of cocaine. Importantly, the inhibitory action was often effective only at high doses of the agonists. The dose-response curves suggest that the stimulation of postsynaptic 5-HT<sub>1A</sub> receptors is required for the inhibitory effect.

It was found that cocaine, as well as cocaine-associated cues, can reinstate self-administration in rats (De Wit and Stewart, 1981; Shaham *et al.*, 2003). Schenk (2000) investigated the effects of the 5-HT<sub>1A</sub> receptor antagonist WAY 100635 on cocaine-induced reinstatement of cocaine-seeking behavior in rats. Pre-treatment with WAY 100635 blocked the reinstatement of cocaine-seeking by an injection of cocaine. The same dose of WAY 100635 did not affect oral self-administration of the artificial sweetener saccharin, thus indicating that WAY 100635 did not induce a generalized anhedonia (Schenk, 2000). In contrast to the attenuating effects on cocaine-induced reinstatement of cocaine-seeking behavior in rats, WAY 100635 (0.1–1.0 mg/kg, s.c.) did not affect the reinstatement elicited by a cocaine-associated cue (Cervo *et al.*, 2003). Both findings were replicated in a study by Burmeister *et al.* (2004). The authors reported a failure of WAY 100635 to block cue-induced reinstatement of cocaine-seeking, but an attenuating effect of the same doses on the cocaine-induced reinstatement of cocaine-seeking behavior (Burmeister *et al.*, 2004). In summary, the available data suggest a facilitatory role for 5-HT<sub>1A</sub> receptors in the reinstatement of cocaine-seeking behavior induced by cocaine, but not when induced by sensory cues.

### 5-HT<sub>1B</sub> receptor

The 5-HT<sub>1B</sub> receptor was shown to facilitate cocaine-induced hyperlocomotion in rats and mice (Seršen *et al.*, 1996; Castanon *et al.*, 2000; Przegalinski *et al.*, 2001a; Hoplight *et al.*, 2005). However, using 5-HT<sub>1B</sub> receptor knockout mice, suppressory effects were found for cocaine-induced hyperlocomotion (Rocha *et al.*, 1998). At the local level, fewer regional dissociations and deviations from systemic effects were observed for the 5-HT<sub>1B</sub> receptor compared with the 5-HT<sub>1A</sub> receptor. Pharmacological evidence suggests a facilitatory role of 5-HT<sub>1B</sub> receptors in the Nac/shell in cocaine-induced hyperlocomotion (Przegalinski *et al.*, 2002), which mimics systemic effects. In contrast, no effect was found when Nac/core 5-HT<sub>1B</sub> receptors were activated (Przegalinski *et al.*, 2002). Przegalinski *et al.* (2004) observed a potentiation of cocaine-induced hyperlocomotion by intra-VTA pre-treatment with the 5-HT<sub>1B</sub> receptor agonist CP 93129. In rats with a viral vector-mediated local over-expression of 5-HT<sub>1B</sub> receptors in the VTA, cocaine-induced hyperlocomotion was also increased, which might suggest a facilitatory role for VTA 5-HT<sub>1B</sub> receptors (Neumaier *et al.*, 2002).

The 5-HT<sub>1B</sub> receptor contributed to neither the establishment nor the expression of locomotor sensitization in rats (Przegalinski *et al.*, 2001a). In 5-HT<sub>1B</sub> receptor knockout mice, however, suppressory effects on the establishment of sensitization were reported (Rocha *et al.*, 1998). 5-HT<sub>1B</sub> receptors in the Nac/shell facilitate the establishment as well as the expression of locomotor sensitization, while in the VTA 5-HT<sub>1B</sub> receptors only contribute to the establishment but not to the expression. Nac/core 5-HT<sub>1B</sub> receptors are not involved in locomotor sensitization (Przegalinski *et al.*, 2002, 2004).

Systemic 5-HT<sub>1B</sub> receptor stimulation with the receptor agonist RU 24969 partially substitutes for cocaine (Callahan and Cunningham, 1995), although with a temporal restriction (Parsons *et al.*, 1998). 5-HT<sub>1B</sub> receptor stimulation with RU 24969 or CP 94,253 was also found to contribute to the discriminative stimulus properties of cocaine at the systemic level (Callahan and Cunningham 1997; Filip *et al.*, 2001a). In contrast to the systemic effects, neither VTA nor Nac/core or Nac/shell 5-HT<sub>1B</sub> receptor stimulation with CP 93129 substituted for cocaine. This suggests that the partial substitution observed at the systemic level is mediated by other 5-HT<sub>1B</sub> receptor populations. VTA and Nac/core, but not Nac/shell, 5-HT<sub>1B</sub> receptors contribute to the discriminative stimulus properties of cocaine (Filip *et al.*, 2002, 2003).

Pharmacological and transgenic approaches support a facilitatory role for 5-HT<sub>1B</sub> receptors in the establishment

of cocaine-induced CPP in rats as well as in mice (Belzung *et al.*, 2000; Cervo *et al.*, 2002). However, a potentiation of cocaine-induced CPP was only found with the selective 5-HT<sub>1B</sub> receptor agonist CP 94,253 with a low dose of cocaine (Cervo *et al.*, 2002). In rats with a viral vector-mediated local over-expression of 5-HT<sub>1B</sub> receptors in the VTA the dose–response curve for cocaine was shifted to the left in the establishment of a CPP, suggesting a facilitatory role for VTA 5-HT<sub>1B</sub> receptors (Neumaier *et al.*, 2002). Over-expression of 5-HT<sub>1B</sub> receptors in the Nac/shell also enhanced cocaine-induced CPP, but also the delayed aversive effects of cocaine (Barot *et al.*, 2007).

The self-administration of cocaine in rats was facilitated by pre-treatment with the 5-HT<sub>1B</sub> receptor agonist RU 24969 (Parsons *et al.*, 1998) but inhibited by the agonist CP94253 (Przegalinski *et al.*, 2007). In this study, the 5-HT<sub>1B</sub> receptor antagonist SB 216641 did not affect cocaine self-administration. Pre-treatment with the selective 5-HT<sub>1B</sub> receptor antagonist GR 127,935 blocked self-administration in mice when cocaine was administered into the VTA (David *et al.*, 2004). In contrast, in 5-HT<sub>1B</sub> receptor KO mice a potentiated cocaine self-administration was observed compared to wild-type mice (Rocha *et al.*, 1998). Cue- as well as cocaine-induced reinstatement of cocaine self-administration was blocked by 5-HT<sub>1B</sub> receptor activation (Acosta *et al.*, 2005).

### 5-HT<sub>2A</sub> receptor

Several studies, using selective 5-HT<sub>2A</sub> receptor agonists and antagonists, suggest a facilitatory role of the 5-HT<sub>2A</sub> receptor in cocaine-induced hyperlocomotion at a systemic level (O'Neill *et al.*, 1999; Fletcher *et al.*, 2002a). A study on local 5-HT<sub>2A</sub> receptor effects applied the selective antagonist M 100,907 into the VTA or Nac/shell, and provided evidence for a facilitatory contribution of VTA but not Nac/shell 5-HT<sub>2A</sub> receptors to cocaine-induced hyperlocomotion (McMahon *et al.*, 2001). Thus the VTA but not Nac/shell 5-HT<sub>2A</sub> receptor effects concur with the systemic contribution of this receptor to cocaine-induced hyperlocomotion.

5-HT<sub>2A</sub> receptors also facilitate the expression of locomotor sensitization, while they are not involved in its establishment (Davidson *et al.*, 2002; Filip *et al.*, 2004). Neither 5-HT<sub>2A</sub> receptor agonism nor antagonism substitutes for cocaine. However, several studies have demonstrated a contribution to the discriminative stimulus properties of cocaine in rats and monkeys (Schama *et al.*, 1997; Munzar *et al.*, 2002; Filip *et al.*, 2006). There is no evidence for a role of 5-HT<sub>2A</sub> receptors in cocaine self-administration in rats (Howell and Byrd, 1995; Fletcher

*et al.*, 2002a). However, high doses of the 5-HT<sub>2A</sub> receptor antagonist MDL100907 might produce a downward shift in the dose–effect curve of cocaine (Fantegrossi *et al.*, 2002). Interestingly, several 5-HT<sub>2A</sub> receptor antagonists can attenuate the reinstatement of cocaine self-administration by cues or cocaine, which might suggest a facilitatory role of the 5-HT<sub>2A</sub> receptor in this behavior (Fletcher *et al.*, 2002a; Burmeister *et al.*, 2004; Filip *et al.*, 2005). At the systemic level, 5-HT<sub>2A</sub> receptors clearly regulate many cocaine-addiction related behaviors.

#### 5-HT<sub>2B</sub> receptor

There is little evidence to suggest a 5-HT<sub>2B</sub> receptor contribution to addiction-related behavior in animal studies. Neither 5-HT<sub>2B</sub> receptor agonism nor antagonism affected cocaine-induced hyperlocomotion or its sensitization at the systemic level (Fletcher *et al.*, 2002b; Filip *et al.*, 2004). Also, 5-HT<sub>2B</sub> receptor antagonism neither substituted for cocaine nor affected its discriminative stimulus properties (Filip *et al.*, 2006). So far, there is no evidence for a contribution of the 5-HT<sub>2B</sub> receptor to any of the cocaine effects on behavior.

#### 5-HT<sub>2C</sub> receptor

The 5-HT<sub>2C</sub> receptor is the only presently known 5-HT receptor subtype which predominantly attenuates several core addiction-related behaviors of cocaine at the systemic level. The pharmacological approach in rats as well as the 5-HT<sub>2C</sub> receptor KO approach in mice provide convincing evidence for a sustained inhibitory role of 5-HT<sub>2C</sub> receptors at the systemic level in cocaine-induced hyperlocomotion (Fletcher *et al.*, 2006; Neisewander and Acosta, 2007), cocaine self-administration, and the cue-, context-, stress- and cocaine-induced reinstatement of cocaine self-administration (Grottick *et al.*, 2000; Fletcher *et al.*, 2002a; Rocha *et al.*, 2002; Burmeister *et al.*, 2004; Filip *et al.*, 2004; Neisewander and Acosta, 2007; Burbassi and Cervo, 2008; Fletcher *et al.*, 2008). In contrast, no evidence for a role in the establishment or expression of locomotor sensitization has been reported (Filip *et al.*, 2004). However, 5-HT<sub>2C</sub> receptors play an inhibitory role in the expression of cocaine-induced conditioned hyperactivity, which was inhibited by pre-treatment with a 5-HT<sub>2C</sub> receptor agonist and enhanced by an antagonist (Liu and Cunningham, 2006).

Neither systemic 5-HT<sub>2C</sub> receptor agonists nor antagonists substituted for cocaine (Callahan and Cunningham, 1997; Frankel and Cunningham, 2004; Filip *et al.*, 2006). Nevertheless, there is evidence for an attenuation of cocaine's discriminative stimulus properties by 5-HT<sub>2C</sub> receptor activation (Callahan and Cunningham, 1997; Frankel and

Cunningham, 2004), and evidence for an enhancement by 5-HT<sub>2C</sub> receptor antagonism (Filip *et al.*, 2006).

Moreover, for the 5-HT<sub>2C</sub> receptor considerable local dissociations in the contribution to cocaine-related behaviors have been discovered. Thus, Nac/shell 5-HT<sub>2C</sub> receptors differ in their effects largely from the systemic and other local 5-HT<sub>2C</sub> receptor effects (McMahon *et al.*, 2001). Nac/shell 5-HT<sub>2C</sub> receptor stimulation with the agonists MK 212 and Ro 60-0175 facilitated cocaine-induced hyperlocomotion (Filip and Cunningham, 2003). In contrast, 5-HT<sub>2C</sub> receptor stimulation in the PFC or the VTA blocked cocaine-induced hyperlocomotion, and thus worked in the direction of the systemic effects (Filip and Cunningham, 2003; Fletcher *et al.*, 2004b). In line with the systemic effects, VTA 5-HT<sub>2C</sub> receptors attenuated cocaine self-administration behavior (Fletcher *et al.*, 2004b). Neither Nac/shell nor PFC 5-HT<sub>2C</sub> receptor stimulation substituted for cocaine. However, Nac/shell 5-HT<sub>2C</sub> receptors facilitate the discriminative stimulus properties of cocaine, which is also in opposition to the systemic effects. The PFC 5-HT<sub>2C</sub> receptors seems to work in the other direction, and attenuate them (Filip and Cunningham, 2002, 2003).

#### 5-HT<sub>3</sub> receptor

Several pharmacological studies in rats and mice, using a wide range of 5-HT<sub>3</sub> receptor antagonists, provide evidence for a facilitatory role of the 5-HT<sub>3</sub> receptor in cocaine-induced hyperlocomotion (Reith, 1990; Kankaanpää *et al.*, 2002). Such a role has been confirmed by a transgenic approach, which used 5-HT<sub>3</sub> receptor over-expressing mice (Allan *et al.*, 2001). However, 5-HT<sub>3</sub> receptor KO mice did not differ in their acute hyperlocomotor effects from wild types after different doses of cocaine (Hodge *et al.*, 2008). At the local level of the Nac, application of the 5-HT<sub>3</sub> receptor antagonist ondansetron attenuated cocaine-induced hyperactivity (Herges and Taylor, 2000), which suggests a permissive role for Nac 5-HT<sub>3</sub> receptors in this cocaine effect. Such a role would be largely congruent with the systemic effects.

In rats, 5-HT<sub>3</sub> receptors were found to contribute to the expression (Davidson *et al.* 2002, 2004, 2007; Zhang *et al.*, 2007) but not to the establishment (Szumlinski *et al.*, 2003) of locomotor sensitization. A study in 5-HT<sub>3</sub> receptor KO mice reported an attenuated establishment of cocaine sensitization, but no differences in conditioned hyperlocomotion, following a saline challenge after cocaine sensitization (Hodge *et al.*, 2008).

5-HT<sub>3</sub> receptor stimulation with the receptor agonist mCPBG partially substitutes for cocaine, but only minimally modulated its discriminative stimulus properties (Koetznner *et al.*, 1995; De La Garza *et al.*, 1996),

although various 5-HT<sub>3</sub> receptor antagonists failed to modulate either parameter (Paris and Cunningham, 1991; Lane *et al.*, 1992).

Pharmacological studies with the 5-HT<sub>3</sub> receptor antagonists MDL 72222 and ICS 205-930 suggest a facilitatory role in the establishment of CPP (Suzuki *et al.*, 1992; Kankaanpää *et al.*, 2002), but not in CPP expression (Cervo *et al.*, 1996; Kankaanpää *et al.*, 2002). A study using 5-HT<sub>3</sub> receptor over-expressing mice, however, suggested an inhibitory role (Allan *et al.*, 2001).

The 5-HT<sub>3</sub> receptor seems not to contribute to cocaine self-administration and its reinstatement by cues (Lane *et al.*, 1992; Davidson *et al.*, 2002, 2004). However, when the 5-HT<sub>3</sub> receptor was blocked with ondansetron after an oral self-administration session, it reduced cocaine intake on the following day (Davidson *et al.*, 2004). Likewise, it reduced the resumption of i.v. cocaine self-administration after a withdrawal period in rats (Davidson *et al.*, 2002). Interestingly, VTA 5-HT<sub>3</sub> receptor antagonism with ICS 205-930 attenuated cocaine self-administration into the VTA (Rodd *et al.*, 2005), which is in contrast to the systemic effects.

#### 5-HT<sub>4</sub> receptor

While systemic application of the 5-HT<sub>4</sub> receptor partial agonist RS 67333 did not affect cocaine-induced hyperlocomotion, the receptor antagonist SDZ 205,557 attenuated this cocaine effect (McMahon and Cunningham, 1999). These findings might suggest a permissive, but not a potentiating, role for 5-HT<sub>4</sub> receptors at a systemic level in the locomotor effects of cocaine. In the same study, the role of Nac/shell 5-HT<sub>4</sub> receptors was investigated. Agonism as well as antagonism of the Nac/shell 5-HT<sub>4</sub> receptors attenuated cocaine-induced hyperlocomotion (McMahon and Cunningham, 1999).

#### 5-HT<sub>6</sub> receptor

A study on the role of the 5-HT<sub>6</sub> receptor did not provide evidence for a contribution at the systemic level to cocaine-induced hyperlocomotion or self-administration (Frantz *et al.*, 2002). In line with this are findings which show that the 5-HT<sub>6</sub> receptor antagonist MS-245 did not substitute for cocaine, or modulate its discriminative stimulus properties (Pullagurla *et al.*, 2004). However, a recent study using viral-mediated 5-HT<sub>6</sub> receptor over-expression in the Nac/shell found an inhibitory effect on the establishment of cocaine-induced CPP, but no effect on cocaine-induced hyperlocomotion or the sensitization of hyperlocomotion (Ferguson *et al.*, 2008). In line with this were pharmacological findings with the 5-HT<sub>6</sub> receptor antagonist Ro4368545, which facilitated cocaine-induced CPP (Ferguson *et al.*, 2008). Clearly, the role of

the 5-HT<sub>6</sub> receptor in cocaine addiction requires further research.

#### Human studies

The effects of 5-HT depletion on acute subjective effects of cocaine were investigated in humans (Aronson *et al.*, 1995). Each of 12 subjects, who were all DSM-III-R diagnosed for cocaine dependence, were given two low-tryptophan diet pre-treatments, a placebo and a sham pre-treatment, each followed by an intranasal test-dose of cocaine. The subjective rating of the 'high' after cocaine was 20 percent lower during tryptophan depletion than during sham depletion. The depletion itself did not have significant effects on mood in this study. These results suggest a role for 5-HT in the acute euphoric effects of cocaine. However, it is not clear how far the effects are related to cocaine craving or self-administration. Satel *et al.* (1995) found, in a study of cocaine-dependent inpatients, an attenuation of cue-induced cocaine craving after drinking an amino acid cocktail that was devoid of tryptophan.

Walsh *et al.* (1994) investigated the effects of the SSRI, fluoxetine, on the subjective effects of a cocaine challenge in volunteers with a history of cocaine abuse. Fluoxetine or placebo was administered for 4 weeks before subjects were challenged with either cocaine (i.v.) or saline. It was found that fluoxetine dose-dependently attenuated the cocaine effects on subjective measures, such as 'liking', 'rush' and 'good effects'. Although fluoxetine reduced the hedonic effects of cocaine, its application as a treatment for cocaine addiction yielded inconsistent results. In a study with cocaine-dependent patients, Grabowski *et al.* (1995) reported a transient reduction of the cocaine consumption in a fluoxetine-treated group, while another study in crack cocaine-dependent outpatients did not find reduced cocaine use or cocaine craving in a fluoxetine-treated group compared to a placebo group (Batki *et al.*, 1996). Covi *et al.* (1995) even found increased cocaine consumption in patients treated with a high dose of fluoxetine in a 12-week trial compared to placebo-treated patients. Moeller *et al.* (2007) investigated the effects of the SSRI citalopram in combination with behavioral therapy and contingency management in 76 cocaine-dependent patients. In this study, citalopram-treated subjects showed a significant increase in abstinence rates as measured by a reduction of cocaine-positive urine samples. Increased 5-HT availability induced by a diet enriched in tryptophan and tyrosine had no effect on cocaine craving in humans. In a double-blind study, Chadwick *et al.* (1990) used a supplementary tryptophan and tyrosine diet in cocaine-dependent subjects in order to investigate the effects

of an increased 5-HT level on drug craving. They did not find significant differences in drug-craving and other subjective syndromes compared to a placebo-treated control group.

No compelling evidence for association of serotonin receptors in cocaine abuse and dependence has been presented in the few studies published to date. No association of cocaine abuse with seven SNPs in the 5-HT<sub>1B</sub> gene (Cigler *et al.*, 2001), the 5-HT<sub>1B</sub> gene in Han Chinese, the serotonin transporter (5-HTT) (Patkar *et al.*, 2002) in African Americans and the tryptophan hydroxylase 2 (TPH2) gene in African Americans (Dahl *et al.*, 2006) could be observed. By today's standards, however, these studies were underpowered, and SNP selection procedures were less rigorous and systematic than current procedures, thus indicating the need for larger, well-designed studies in this area.

The investigation of single receptor subtypes in terms of their contribution to the hedonic effects of cocaine is restricted by the limited availability of selective 5-HT receptor ligands that can be applied in humans in a therapy setting. However, there are some preliminary reports that suggest a reduction of cocaine's subjective effects in humans by the 5-HT<sub>2</sub> antagonist ritanserin and the 5-HT<sub>3</sub> antagonist ondansetron (Walsh and Cunningham, 1997). At present, very little is known about the contribution of other 5-HT receptor subtypes to the subjective effects of cocaine. Only very few 5-HT receptor ligands have been tested as complementary treatments for cocaine addiction. Ehrman *et al.* (1996) investigated the 5-HT<sub>2</sub> antagonist ritanserin in a double-blind study in patients on cue-elicited cocaine craving. Ritanserin did not affect the cue-induced 'high' or craving. These results were confirmed by Cornish *et al.* (2001), who used ritanserin or placebo as an adjunct therapy in cocaine-dependent outpatients for a 4-week period. Also in this study, ritanserin failed to reduce craving in a therapeutic application in cocaine addicts.

### ***The 5-HT system in cocaine addiction***

The role of 5-HT in cocaine addiction has been investigated with great effort. While basic 5-HT activity is required for all sorts of behavior (including addiction-related), global manipulation of the 5-HT system has shown that a strong increase in extracellular 5-HT activity quite uniformly inhibits crucial addiction-related behaviors, while 5-HT depletion enhances them. Does this mean that the 5-HT increase observed in virtually all brain areas measured so far is a purely limiting factor for cocaine addiction that only counteracts, for example, the prominent DA effects (Di Chiara and Imperato,

1988)? The answer is probably 'no', with a more sophisticated approach lying in the decomposition of local 5-HT effects. It appears that the 5-HT response has to be in balance with the DA (and possibly noradrenergic) response to fully express cocaine addiction-related behaviors. If this balance is changed towards or away from 5-HT, it can modify the behavioral effects of the drug in either way (see, for example, Rothman *et al.*, 2006; Carey *et al.*, 2008). Most of the investigated 5-HT receptors contribute to cocaine addiction-related behaviors. Interestingly, for most receptors this contribution is facilitating for one addiction-related behavior but inhibitory for others. Exceptions to this 'rule' seem to be the 5-HT<sub>2A</sub>- and 5-HT<sub>2C</sub> receptors. While 5-HT<sub>2A</sub> receptors tend to facilitate addiction-related behaviors, 5-HT<sub>2C</sub> receptor stimulation constantly inhibits many of them. This would make 5-HT<sub>2C</sub> agonism a desirable treatment approach for cocaine addiction. However, the prominent anxiogenic effects of 5-HT<sub>2C</sub> receptor agonists are still limiting this approach in humans (however, for an alternative approach see Ji *et al.*, 2006; Müller and Carey, 2006).

Using the preclinical findings for pharmacological approaches in human cocaine addiction, therapy has not proven successful yet. The available evidence suggests that the relatively crude approach of increasing 5-HT activity with either precursors or SSRI treatment does not work. Also, unspecific 5-HT<sub>2</sub>- and 5-HT<sub>3</sub>-receptor ligands did not yield significant improvement. Considering the pre-clinical evidence, the most promising target within the 5-HT system is probably the 5-HT<sub>2C</sub> receptor, given that mechanisms can be found to avoid the aversive effects of the agonists that quite certainly would limit patient compliance.

## **Amphetamine**

### ***The neurochemical effects of amphetamine on 5-HT***

The synthetic substance amphetamine occurs as stereo isomers d- and l-amphetamine, or as the racemic mixture. Notably, the d- or (+) isomer is usually more potent at the behavioral and neurochemical level, and is more often used for scientific investigation. Amphetamine increases extracellular 5-HT levels in the Nac and the striatum, parallel to the expression of hyperlocomotion and behavioral stereotypies (Hernandez *et al.*, 1987; Kuczenski and Segal, 1989, 1997; Kuczenski *et al.*, 1995; Kankaanpää *et al.*, 1998; Millan *et al.*, 1999). An amphetamine-induced 5-HT increase was also observed in the frontal cortex (FC) (Millan *et al.*, 1999), in the mPFC (Kuroki *et al.*, 1996; Pum *et al.*, 2007) and in the entorhinal and perirhinal cortices parallel to locomotor activation

(Pum *et al.*, 2007). Increased extracellular 5-HT levels were reported in the DRN during local amphetamine application (Ferre *et al.*, 1994), but not in the striatum (Dawson *et al.*, 2003). Local application of amphetamine by reverse dialysis into the infralimbic and anterior cingular subregions of the PFC also increases extracellular 5-HT levels in the respective regions (Hedou *et al.*, 2000). Also at the neurochemical level, d-amphetamine appears to be more potent than l-amphetamine (Kuczenski *et al.*, 1995; Seiden *et al.*, 1993). As for cocaine, amphetamine's acute effects on 5-HT suggest significant modulation of the behavioral and subjective effects.

### **Reducing and potentiating 5-HT activity**

Studies using global 5,7-DHT lesions found attenuation (Lipska *et al.*, 1992) or no effect (Gately *et al.*, 1985) on amphetamine-induced hyperactivity. Local lesion studies found no effect when 5,7-DHT was injected into amygdala regions (Kusljic and van den Buuse, 2006), the ventral hippocampus (Adams *et al.*, 2008) or the MRN and/or DRN (Lehmann *et al.*, 2000; Kusljic *et al.*, 2003), but significant attenuation when injected in the fimbria-fornix/cingular bundle (Lehmann *et al.*, 2000). Pre-treatment with the SSRIs fluoxetine and citalopram had either no effect (Maj *et al.*, 1996) or, with fluoxetine and sertraline, enhanced the acute hyperlocomotor effects of amphetamine in rats (Sills *et al.*, 1999a, b, 2000). However, SSRI effects must be interpreted with some caution, since they were also observed after combined 5,7-DHT lesions of the MRN and DRN. Both SSRIs also enhanced CNS concentrations of amphetamine, possibly by decreasing the amphetamine metabolism. These findings suggest a non-serotonergic mechanism in the potentiation of the amphetamine effects (Sills *et al.*, 1999a, b, 2000).

Reducing brain 5-HT availability by 5,7-DHT injection into the medial forebrain bundle or i.c.v. did not affect the establishment of amphetamine self-administration behavior, but resulted in higher drug-taking per session (Lyness *et al.*, 1980; Leccese and Lyness, 1984). Other studies, however, did not find any changes in d-amphetamine self-administration after a profound reduction of brain serotonin following DRN and MRN lesions with 5,7-DHT (Fletcher *et al.*, 1999), or after local lesion in the Nac (Lyness *et al.*, 1980). Enhancing the 5-HT availability by pre-treatment with the precursor L-tryptophan or the SSRI fluoxetine reduced responding for amphetamine and amphetamine self-administration in rats (Leccese and Lyness, 1984; Smith *et al.*, 1986; Yu *et al.*, 1986; Porrino *et al.*, 1989). Also, the direct injection of 5-HT into the Nac reduced amphetamine self-administration in rats (Fletcher

*et al.*, 2002b), which might at least suggest a restrictive function of 5-HT when activated.

The SSRIs fluoxetine and paroxetine did not affect the increase in brain-stimulation reward threshold after withdrawal from repeated amphetamine administration in rats. Nevertheless, a high dose of fluoxetine could reduce the duration of the withdrawal-induced elevation of ICSS thresholds (Harrison *et al.*, 2001; Markou *et al.*, 2005).

### **5-HT receptors**

#### **5-HT<sub>1A</sub> receptor**

Amphetamine can increase locomotor activity at low to medium doses, but causes behavioral stereotypies at higher doses (Segal, 1975; Geyer *et al.*, 1987; Paulus *et al.*, 1993; Kuczenski and Segal, 1999). Partial and full 5-HT<sub>1A</sub> receptor agonists blocked the hyperlocomotion induced by d-amphetamine in mice and rats (Maj *et al.*, 1987; Przegalinski and Filip, 1997; Millan *et al.*, 1998). While the non-selective 5-HT<sub>1A</sub> receptor agonist buspirone blocked the hyperlocomotor effects of amphetamine in one study, the application of the selective agonist 8-OH-DPAT significantly potentiated the hyperlocomotor effects of amphetamine (Jackson *et al.*, 1994). The selective 5-HT<sub>1A</sub> receptor antagonist WAY 100135 failed to influence hyperlocomotion induced by amphetamine (Przegalinski and Filip, 1997). Layer *et al.* (1992), in contrast, reported a marked inhibition of d-amphetamine stimulated locomotor activity by the 5-HT<sub>1A</sub> receptor antagonist NAN-190 in rats. A local application study found a facilitatory role of the 5-HT<sub>1A</sub> receptor in the Nac in d-amphetamine-induced hyperlocomotion (Layer *et al.*, 1992). Overall, the available studies support the view that 5-HT<sub>1A</sub> receptors are essentially involved in acute amphetamine-induced hyperlocomotion, while the direction of effect might depend on 5-HT<sub>1A</sub> receptor subtype activation.

Przegalinski *et al.* (2000) found that the 5-HT<sub>1A</sub> receptor agonist 8-OH-DPAT blocked the induction as well as the expression of amphetamine-induced sensitization. While these effects were reversed by WAY 100135, the antagonist alone did not have an influence.

Amphetamine can be discriminated from saline in operant tasks (Snoddy and Tessel, 1983). The discriminative stimulus properties of amphetamine were not modulated by 8-OH-DPAT in rats (Przegalinski and Filip, 1997). 8-OH-DPAT neither generalized to d-amphetamine when given alone, nor antagonized its stimulus effects when given in combination (Young *et al.*, 2006a). However, pre-treatment with 8-OH-DPAT appeared to potentiate the discriminative stimulus properties of a sub-threshold dose of d-amphetamine. The authors concluded that

d-amphetamine is a more effective discriminative stimulus in the presence of 8-OH-DPAT (Young *et al.*, 2006a). A study in rhesus monkeys found no substitution for the effects of intra-gastrically applied amphetamine by the 5-HT<sub>1A</sub> receptor agonists buspirone, gepirone or 8-OH-DPAT. Nevertheless, this study reported inhibition of the discriminative stimulus properties of amphetamine (Nader and Woolverton, 1994). The potency to block the amphetamine discriminative stimulus effects was 8-OH-DPAT > buspirone > gepirone. Considering the high effectiveness of 8-OH-DPAT in this study, the ED<sub>50</sub> suggests that the observed effects may be primarily mediated by 5-HT<sub>1A</sub> autoreceptor activation rather than by affecting all 5-HT<sub>1A</sub> receptor populations of the brain. In contrast, the lack of an amphetamine substitution was evident at much higher doses of 8-OH-DPAT, which are known to affect 5-HT<sub>1A</sub> autoreceptors and postsynaptic 5-HT<sub>1A</sub> receptors (Nader and Woolverton, 1994). Also, the studies that failed to find an inhibitory effect for 8-OH-DPAT used concentrations in this range. Thus, it may be speculated that some of the seemingly contradictory findings might be due to dose differences, which result in the preferential activation of 5-HT<sub>1A</sub> autoreceptors at low doses, or in the activation of 5-HT<sub>1A</sub> autoreceptors and postsynaptic receptors at higher doses. Accordingly, the present data suggest that 5-HT<sub>1A</sub> autoreceptors in the raphe nuclei might inhibit the discriminative stimulus properties of amphetamine. This effect, however, may be cancelled out by the additional activation of (some) postsynaptic 5-HT<sub>1A</sub> receptor populations. Most studies show that 5-HT<sub>1A</sub> receptor agonists do not substitute for amphetamine, and 5-HT<sub>1A</sub> receptor antagonists do not modulate the discriminative stimulus properties.

Amphetamine induces a profound CPP in animals (Bardo and Bevins, 2000; Tzschentke, 2007). A CPP study in mice showed that the 5-HT<sub>1A</sub> receptor antagonist WAY 100635 (2 mg/kg, i.p.) did not affect the establishment of amphetamine-induced CPP (Budygin *et al.*, 2004).

Several studies have shown drug-seeking and self-administration of amphetamine in rodents (Yokel and Pickens, 1973) and monkeys (Johanson *et al.*, 1976; Ritz and Kuhar, 1989) under different schedules of reinforcement. The role of 5-HT<sub>1A</sub> receptors in the self-administration of amphetamine and its derivatives, however, has received little attention. A study by Fletcher *et al.* (2002b) showed that intra-Nac application of 8-OH-DPAT did not affect the self-administration of d-amphetamine in rats in a progressive-ratio schedule of reinforcement.

During withdrawal, thresholds to maintain intracranial self-stimulation were increased in rats. This indicates a higher reward threshold in the brain consistent with a decreased hedonic tone (Markou *et al.*, 2005).

The 5-HT<sub>1A</sub> receptor antagonist p-MPPI did not affect the increase in the brain-stimulation reward threshold after withdrawal from repeated amphetamine administration in rats. However, co-administration of the SSRIs paroxetine or fluoxetine with p-MPPI reduced the duration of the reward deficits significantly (Harrison *et al.*, 2001; Markou *et al.*, 2005). Although very little is known about the role of 5-HT<sub>1A</sub> receptors in psychostimulant withdrawal effects, the present data suggest a possible beneficial effect when administered in combination with a treatment that increases 5-HT activity.

### 5-HT<sub>1B</sub> receptor

5-HT<sub>1B</sub> receptor stimulation was found to enhance d-amphetamine-induced locomotor stimulation (Fletcher and Korth, 1999; Przegalinski *et al.*, 2001b; but see also Layer *et al.*, 1992), while 5-HT<sub>1B</sub> receptor antagonism inhibited it (Przegalinski *et al.*, 2001b) or had no significant effect (Chaouloff *et al.*, 1999).

The establishment, but not the expression, of amphetamine-induced sensitization was blocked by 5-HT<sub>1B</sub> receptor antagonism and facilitated by the agonism (Przegalinski *et al.*, 2001b). Although not necessary for the hyperlocomotor effects of amphetamine, 5-HT<sub>1B</sub> receptors in the VTA were able to enhance the amphetamine effects when pharmacologically stimulated (Papla *et al.*, 2002). Surprisingly, 5-HT<sub>1B</sub> receptor KO mice showed enhanced acute effects of amphetamine and a more pronounced establishment of the sensitization than wild types (Bronsert *et al.*, 2001). Altogether, the majority of pharmacological studies suggest a facilitatory role for 5-HT<sub>1B</sub> receptor stimulation in the acute hyperlocomotor effects of amphetamine as well as in the establishment of their sensitization.

A partial generalization for the amphetamine stimulus by two 5-HT<sub>1B</sub> receptor agonists was found in a conditioned taste aversion paradigm in rats. Agonist pre-treatment also enhanced the discriminative stimulus properties of amphetamine. 5-HT<sub>1B</sub> receptor antagonism neither generalized to amphetamine, nor affected its discriminative stimulus properties (Miranda *et al.*, 2007). A local stimulation study did not find evidence for a role of 5-HT<sub>1B</sub> receptors in the Nac/shell in the discriminative stimulus effects of amphetamine (Filip *et al.*, 2001b), supporting the view that 5-HT<sub>1B</sub> receptors do not play a major role in this amphetamine effect.

The 5-HT<sub>1B/1A</sub> receptor agonist RU-24969 reduced d-amphetamine self-administration. This effect was reversed by a 5-HT<sub>1B/1D</sub> antagonist, but not by a selective 5-HT<sub>1A</sub> receptor antagonist (Fletcher and Korth, 1999). Fletcher *et al.* (2002b) identified the Nac as one site of 5-HT<sub>1B</sub> receptor action. Local application of a 5-HT<sub>1B</sub>

receptor agonist into the Nac inhibited amphetamine self-administration in this study.

#### *5-HT<sub>2A</sub> receptor*

A number of studies showed that the 5-HT<sub>2A</sub> receptor antagonist MDL 100907 inhibited the locomotor stimulant effects of amphetamine in rats and mice (Sorensen *et al.*, 1993; Moser *et al.*, 1996; O'Neill *et al.*, 1999; but see also Carlsson *et al.*, 1999), but did not affect its discriminative stimulus properties in rats (Moser *et al.*, 1996). The acute hyperlocomotor effect of amphetamine, but not its sensitization, was potentiated in 5-HT<sub>2A</sub> receptor KO mice. This paradoxical effect, however, was accompanied by disruption of the 5-HT<sub>2A</sub> receptor regulation of noradrenergic activity (Salomon *et al.*, 2007). Altogether, there is accumulating evidence for a permissive role of 5-HT<sub>2A</sub> receptors in the locomotor stimulant effects of amphetamine in normal animals. There is no evidence for a role in the sensitization or the discriminative stimulus properties of amphetamine.

#### *5-HT<sub>2C</sub> receptor*

The 5-HT<sub>2C</sub> receptor antagonist SB242084 potentiated amphetamine-induced hyperlocomotion in rats (Fletcher *et al.*, 2006), while the selective 5-HT<sub>2C</sub> receptor agonist WAY-163909 inhibited it (Marquis *et al.*, 2007). These findings suggest an inhibitory role for the 5-HT<sub>2C</sub> receptor in amphetamine-induced hyperlocomotion. No evidence for an effect of 5-HT<sub>2C</sub> receptor antagonism on the establishment of amphetamine-induced hyperlocomotor sensitization was found (Lanteri *et al.*, 2008).

#### *5-HT<sub>3</sub> receptor*

Pharmacological stimulation of the 5-HT<sub>3</sub> receptor was found to enhance the hyperlocomotor effects of d-amphetamine (Layer *et al.*, 1992), while systemic inhibition reduced it in rats (Shankar *et al.*, 2000). Systemic as well as intra-Nac administration of the 5-HT<sub>3</sub> receptor antagonist GR38032F blocked the hyperlocomotor effects of intra-Nac d-amphetamine in rats (Costall *et al.*, 1987). Local application studies suggest a mainly facilitatory role of 5-HT<sub>3</sub> receptors in the VTA, but not in the Nac, in d-amphetamine-induced hyperlocomotion (Gillies *et al.*, 1996). Overall, evidence points to a facilitatory role of 5-HT<sub>3</sub> receptors in amphetamine-induced hyperlocomotion.

A series of 5-HT<sub>3</sub> receptor antagonists was tested to modulate the discriminative stimulus effects of amphetamine in rats. However, none of them blocked the amphetamine effects in this test (Moser, 1992). Another study, though, found a potentiating effect of the 5-HT<sub>3</sub> receptor antagonist ICS 205-930 on the discriminative stimulus

properties of low, but not high, doses of d-amphetamine in rats (West *et al.*, 1995). The partial 5-HT<sub>3</sub> receptor agonist MD-354 did not substitute for d-amphetamine or modify its discriminative stimulus effects. However, it enhanced the discriminative stimulus effects when low doses of d-amphetamine were used (Dukat *et al.*, 2007). There was no effect of 5-HT<sub>3</sub> receptor antagonism on amphetamine-induced CPP (Acquas *et al.*, 1988; Carboni *et al.*, 1988).

#### *5-HT<sub>4</sub> and 5-HT<sub>6</sub> receptors*

The 5-HT<sub>4</sub> receptor antagonist SB-204070-A did not affect amphetamine-induced hyperlocomotion in rats, suggesting no contribution of the 5-HT<sub>4</sub> receptor to this amphetamine-induced behavior (Reavill *et al.*, 1998). The 5-HT<sub>6</sub> receptor antagonist MS-245 did not substitute for d-amphetamine, but enhanced the discriminative stimulus properties of a low dose of d-amphetamine (Pullagurra *et al.*, 2004).

### *Human studies*

The efficacy of the 5-HT<sub>3</sub> receptor antagonist ondansetron to reduce the subjective effects of amphetamine was investigated in nine healthy human volunteers in a double-blind, placebo-controlled, balanced-crossover study. In this study, amphetamine did not change the self-rating of mood but increased self-rating for overall subjective state. This effect was attenuated by ondansetron (Silverstone *et al.*, 1992). Another placebo-controlled study in 10 healthy human volunteers confirmed an inhibitory effect of ondansetron (i.v.) on amphetamine-induced activation-euphoria ratings, although this seemed to depend on the subjects' susceptibility to the amphetamine effects in the first place (Grady *et al.*, 1996). Altogether, there is evidence suggesting a facilitatory contribution of 5-HT<sub>3</sub> receptors to the subjective effects of amphetamine in humans.

### *The 5-HT system in amphetamine addiction*

Compared to cocaine, relatively little is known about the role of 5-HT in amphetamine addiction. However, at the neurochemical level, amphetamine also induces a profound activation of the 5-HT system, thus suggesting mechanisms similar to those of cocaine. Global 5-HT manipulations have similar effects on amphetamine- and cocaine-related behaviors: 5-HT enrichment inhibits some important addiction-related behaviors. However, this strategy has not been tested in a clinical setting. The knowledge about single receptor contributions is much

more limited for amphetamine. We still lack information on crucial paradigms such as CPP and self-administration, and their reinstatement after withdrawal, as well as on local effects of these receptors. Although inhibitory effects of a 5-HT<sub>3</sub> receptor antagonist on the acute subjective effects of amphetamine were repeatedly found in humans, there is as yet not sufficient direct evidence that suggests the use of any 5-HT receptor ligand for the treatment of amphetamine addiction in humans.

## Methamphetamine

### *The neurochemical effects of methamphetamine on 5-HT*

The synthetic amphetamine derivative methamphetamine occurs as stereo-isomers and as a racemic mixture. An increase of extracellular 5-HT activity in the Nac and dorsal striatum was reported after methamphetamine application (Kuczenski *et al.*, 1995; Segal and Kuczenski, 1997), with the d-isomer being neurochemically more active than the l-isomer (Kuczenski *et al.*, 1995). d-methamphetamine increased 5-HT levels in the ventral hippocampus of freely moving rats (Rocher and Gardier, 2001). In mice, a 5-HT increase was reported in the PFC after methamphetamine administration (Ago *et al.*, 2006b).

### *Reducing and potentiating 5-HT activity*

Methamphetamine increases locomotor activity with an inverted U-shaped dose–response curve (Witkin *et al.*, 1999). The SSRI fluoxetine did not affect acute methamphetamine-induced hyperlocomotion in mice, but significantly reduced the establishment of methamphetamine sensitization (Takamatsu *et al.*, 2006). Increasing 5-HT availability in the brain by pre-treatment with the monoamine oxidase (MAO)-B inhibitor clorgyline attenuated methamphetamine-induced hyperlocomotion in mice (Kitanaka *et al.*, 2005a). Repeated treatment with the MAO-B inhibitor also blocked the expression of methamphetamine sensitization in mice (Kitanaka *et al.*, 2005b).

The SSRI fluoxetine did not substitute for methamphetamine in rats in a fixed-ratio schedule of food presentation, but shifted the dose–response curve markedly to the left. This effect was blocked by the 5-HT<sub>2A/2C</sub> antagonist ketanserin (Munzar *et al.*, 1999a). In a drug discrimination study in pigeons, the 5-HT releaser fenfluramine, but not the SSRI fluoxetine, produced methamphetamine-appropriate responding (Sasaki *et al.*, 1995).

Fluoxetine independently attenuated the establishment as well as expression of methamphetamine-induced CPP

in mice (Takamatsu *et al.*, 2006). Fenfluramine attenuated the self-administration of methamphetamine in rats. However, this effect developed tolerance after only a few days of treatment (Munzar *et al.*, 1999b).

## 5-HT receptors

### *5-HT<sub>1A</sub> receptor*

A recent study in mice reported an inhibitory effect of the 5-HT<sub>1A</sub> receptor agonist osemozotan on methamphetamine-induced hyperlocomotion (Ago *et al.*, 2006a). Repeated methamphetamine application for 7 days induced a profound sensitization of the hyperlocomotor response in mice. The maintenance of the sensitized response was blocked by twice-daily treatment with osemozotan, as revealed by a challenge injection with methamphetamine 8 days later. The osemozotan effect was antagonized by WAY 100635 (Ago *et al.*, 2006a).

Methamphetamine is discriminated from saline by pigeons and rodents (Sasaki *et al.*, 1995; Witkin *et al.*, 1999). A study in pigeons showed that 8-OH-DPAT at high doses substituted for methamphetamine in at least 50 percent of the animals tested. Low doses of 8-OH-DPAT blocked the discriminative stimulus properties of methamphetamine in pigeons, which might be mediated by presynaptic 5-HT<sub>1A</sub> autoreceptors (Sasaki *et al.*, 1995). However, since only four pigeons were tested, it is difficult to draw sound conclusions from this study concerning effective dose ranges. The systemic application of high doses of 8-OH-DPAT and buspirone partially generalized to a training dose of methamphetamine under a fixed-ratio schedule of food presentation in rats. Effective doses, however, markedly decreased general responding. The partial generalization was antagonized by the 5-HT<sub>1A</sub> receptor antagonist WAY 100635 (Munzar *et al.*, 1999b). At all doses tested, neither 8-OH-DPAT nor buspirone altered the discriminative stimulus properties of methamphetamine in rats. WAY 100635 also failed to affect the methamphetamine discriminative stimulus properties (Munzar *et al.*, 1999b).

### *5-HT<sub>2</sub> receptors*

The unselective 5-HT<sub>2A/2C</sub> agonist DOI showed a partial generalization for methamphetamine at high doses in rats in a fixed-ratio schedule of food presentation, and shifted the dose–response curve to the left when injected 120 minutes before the test session. The unselective 5-HT<sub>2A/2C</sub> antagonist ketanserin shifted the dose–response curve to the right (Munzar *et al.*, 1999b).

### *5-HT<sub>3</sub> receptor*

The acute hyperlocomotor effects of methamphetamine were blocked by pre-treatment with the 5-HT<sub>3</sub> receptor

antagonist MDL 72222 in mice (Yoo *et al.*, 2006). Overexpression of 5-HT<sub>3</sub> receptors in frontal areas of the brain of mice went along with an increased sensitivity to the hyperlocomotor effects of methamphetamine (Allan *et al.*, 2001). These findings suggest a facilitatory role of 5-HT<sub>3</sub> receptors in acute methamphetamine-induced hyperlocomotion. 5-HT<sub>3</sub> receptor antagonism reduced the establishment as well as the expression of methamphetamine-induced locomotor sensitization in mice (Yoo *et al.*, 2006). Neither the 5-HT<sub>3</sub> receptor agonist m-CPBG nor the antagonist tropisetron substituted for the methamphetamine discriminative stimulus in rats. However, tropisetron shifted the dose–response curve significantly to the left (Munzar *et al.*, 1999b). In a drug discrimination study in pigeons, the 5-HT<sub>3</sub> receptor antagonist MDL 72222 partially substituted for methamphetamine, but had no effect when administered together with methamphetamine (Sasaki *et al.*, 1995).

The establishment of methamphetamine-induced CPP was blocked by the 5-HT<sub>3</sub> receptor antagonists MDL 72222 and ICS 205-930, which suggests a facilitatory role of the 5-HT<sub>3</sub> receptor in the motivational properties of methamphetamine (Suzuki *et al.*, 1992).

### **Human studies**

Based on the findings in animals, Johnson and colleagues (2008) investigated whether the 5-HT<sub>3</sub> receptor antagonist ondansetron would be superior to placebo in reducing methamphetamine use in 150 methamphetamine-dependent men and women. In this multi-site randomized, double-blind, placebo-controlled study, ondansetron (three doses) or placebo (p.o.) were given for 8 weeks in combination with cognitive behavioral therapy. The primary outcome measure was the number of methamphetamine-free study weeks assessed by methamphetamine-free urine samples. Although ondansetron was tolerated well, there was no difference between the ondansetron and placebo groups in the primary outcome measure. Also, secondary measures such as methamphetamine urine levels and self-reported non-use or achievement were not improved by ondansetron (Johnson *et al.*, 2008).

### **The 5-HT system in methamphetamine addiction**

Methamphetamine reliably increases 5-HT activity in the brain. Similar to cocaine and amphetamine, increasing the 5-HT activity before drug administration inhibited several addiction-related behaviors. However, crucial behaviors still need to be investigated. The knowledge regarding 5-HT receptor contribution to the methamphetamine

behavioral effects is still very limited, basically being restricted to the 5-HT<sub>1A</sub> and 5-HT<sub>3</sub> receptors. While pre-clinical findings with the 5-HT<sub>3</sub> receptor suggested an application of the antagonist for addiction treatment, a recent clinical trial did not succeed in finding beneficial effects in human methamphetamine addicts. In the light of the findings with cocaine, investigating the role of the 5-HT<sub>2A</sub> and 5-HT<sub>2C</sub> receptors in methamphetamine addiction could be a promising future goal.

## **MDMA**

### ***The neurochemical effects of MDMA on 5-HT***

Methylenedioxymethamphetamine (MDMA, ecstasy) is a synthetic amphetamine derivative with the stereo isomers (+)MDMA and (–)MDMA (Green *et al.*, 2003). MDMA increases extracellular 5-HT activity in the Nac (Kankaanpää *et al.*, 1998; Trigo *et al.*, 2007; Baumann *et al.*, 2008; Doly *et al.*, 2008), striatum (Gough *et al.*, 1991; Sabol and Seiden, 1998; Baumann *et al.*, 2008), VTA (Doly *et al.*, 2008), SN (Yamamoto *et al.*, 1995), hippocampus (Gartside *et al.*, 1997; Mehan *et al.*, 2002) and FC (Gartside *et al.*, 1997; Trigo *et al.*, 2007; Baumann *et al.*, 2008), as measured by *in vivo* microdialysis studies in rats, or in superfused rat brain slices (Schmidt *et al.*, 1987). Microdialysis measurements in slice preparations also revealed an increase of extracellular 5-HT levels in the striatum (Koch and Galloway, 1997) and in the DRN (Sprouse *et al.*, 1989, 1990). Altogether, MDMA effects on the 5-HT system suggest a contribution of 5-HT to the acute effects (Baumann *et al.*, 2008).

Interestingly, basal extracellular 5-HT levels in the FC and hippocampus and the 5-HT neuronal firing pattern were not changed after repeated MDMA treatment in rats, when measured 10–12 days after the end of the treatment. However, 5-HT release induced by d-fenfluramine in the FC (Series *et al.*, 1994), and stimulation-evoked 5-HT release in the FC but not in the ventral hippocampus, was markedly decreased after MDMA treatment (Gartside *et al.*, 1996). MDMA exerts potent neurotoxic effects on the 5-HT system (Schmidt, 1987; Schmidt and Taylor, 1988) which are associated with a loss of 5-HT neurons and projections. The 5-HT neurotoxic effects of MDMA are only partially reversible, and may contribute to the long-term behavioral impairments in MDMA users (Quednow *et al.*, 2006, 2007).

### ***Reducing and potentiating 5-HT activity***

An increase in locomotor activity was observed for MDMA (Gold *et al.*, 1988; Callaway *et al.*, 1990;

Bankson and Cunningham, 2001). Both stereoisomers (+)MDMA and (–)MDMA, as well as the racemic mixture (+/–)MDMA, induce hyperlocomotion, with the racemic mixture being the most potent (Fantegrossi *et al.*, 2003). A global lesion of the 5-HT system by 5,7-DHT attenuated (+/–)MDMA-induced locomotor stimulation (Kehne *et al.*, 1996). Pre-treatment with the SSRI fluoxetine also attenuated the hyperlocomotor effect of (+/–)MDMA, but potentiated that of (+)MDMA (Fantegrossi *et al.*, 2003). However, Callaway *et al.* (1990) found that (+)MDMA-induced hyperlocomotion was inhibited by fluoxetine and other SSRIs. Reducing 5-HT activity with the synthesis inhibitor pCPA attenuated the discriminative stimulus properties of MDMA in rats (Schechter, 1991). Strong support for a role of 5-HT in MDMA self-administration was found in mice. SERT KO mice did not self-administer MDMA at any doses tested. MDMA increased DA in the Nac in SERT KO mice and wild types to an equal extent. However, MDMA effects on 5-HT in the PFC were significantly attenuated in the SERT-deficient mice (Trigo *et al.*, 2007).

### 5-HT receptors

#### 5-HT<sub>1A</sub> receptor

Early evidence suggested an inhibitory role of 5-HT<sub>1A</sub> receptor antagonist pre-treatment with propranolol and pindolol on (+)MDMA-induced hyperlocomotion (Callaway *et al.*, 1992; Kehne *et al.*, 1996). However, propranolol and pindolol also display a  $\beta$ -adrenoceptor antagonist profile, which restricts the interpretation of these studies. Subchronic 5-HT<sub>1A</sub> receptor activation with the agonist 8-OH-DPAT for 3 days reduced the hyperlocomotor effects of (+)MDMA when tested 35–37 hours after the last pre-treatment (Callaway and Geyer, 1992). When the effects of the selective 5-HT<sub>1A</sub> receptor antagonist WAY 100635 on (+)MDMA-induced hyperlocomotion were investigated in rats, however, no effect could be found (McCreary *et al.*, 1999). The authors concluded that the 5-HT<sub>1A</sub> receptor is not involved in (+)MDMA-induced locomotor activation (Bankson and Cunningham, 2001).

MDMA can be discriminated from saline by animals in operant tasks (Schechter, 1988; Baker *et al.*, 1997). However, only a minor role for 5-HT<sub>1A</sub> receptors was found regarding the discriminative stimulus properties of MDMA. Stimulation of 5-HT<sub>1A</sub> receptors with 8-OH-DPAT did not substitute for MDMA in rats in a study by Schechter (1988). Another study in rats, however, found a substitution for the MDMA stimulus. A detailed investigation revealed an ED<sub>50</sub> value for racemic 8-OH-DPAT of 0.3 mg/kg, and for the isomers R(+)-8-OH-DPAT and S(–)-8OH-DPAT of 0.2 and 0.4 mg/kg, respectively

(Glennon and Young, 2000). Racemic 8-OH-DPAT, in contrast, did not change the discriminative stimulus properties of MDMA (Glennon and Young, 2000). Pre-treatment with the 5-HT<sub>1A</sub> receptor antagonist NAN-190 slightly attenuated the discriminative stimulus effects of MDMA in rats, but this effect failed to reach statistical significance (Glennon *et al.*, 1992). WAY 1001635 also had little effect on the discrimination of either optical isomer of MDMA (Baker *et al.*, 1997).

#### 5-HT<sub>1B</sub> receptor

5-HT<sub>1B/1D</sub> receptors were shown to play a facilitatory role in MDMA-induced hyperlocomotion (McCreary *et al.*, 1999; Fletcher *et al.*, 2002c). The 5-HT<sub>1B/1D</sub> receptor antagonist GR 127935 blocked the acute hyperlocomotor effects of MDMA in mice. These findings were supported by 5-HT<sub>1B</sub> receptor knockout mice, which showed a reduced hyperlocomotor response to MDMA compared to wild-type mice (Searce-Levie *et al.*, 1999). Subchronic 5-HT<sub>1B</sub> receptor activation with the agonist RU24969 for 3 days, however, reduced the hyperlocomotor effects of (+)MDMA when tested 35–37 hours after the last pre-treatment (Callaway and Geyer, 1992). 5HT<sub>1B/1D</sub> receptors were also found to contribute to the sensitization of the MDMA-induced hyperlocomotion (McCreary *et al.*, 1999).

#### 5-HT<sub>2A</sub> receptor

5-HT<sub>2A</sub> receptors were shown to play a facilitatory role in MDMA-induced hyperlocomotion (McCreary *et al.*, 1999; Fletcher *et al.*, 2002c). MDMA-induced hyperlocomotion was significantly changed by pre-treatment with the selective 5-HT<sub>2A</sub> receptor antagonist MDL100907. 5-HT<sub>2A</sub> receptor antagonism significantly attenuated the hyperlocomotor effects of (+/–)MDMA (Kehne *et al.*, 1996; Fantegrossi *et al.*, 2003; Ball and Rebec, 2005). The role of the 5-HT<sub>2A</sub> receptor in (+)MDMA-induced hyperlocomotion, however, is still unclear. Fantegrossi *et al.* (2003) reported potentiating effects of the 5-HT<sub>2A</sub> receptor antagonist MDL100907, while Herin *et al.* (2005) found an attenuation of (+)MDMA-induced hyperlocomotion. (+)MDMA and (–)MDMA, as well as the racemic mixture (+/–)MDMA, are self-administered by rodents and primates (Fantegrossi *et al.*, 2002, 2003). 5-HT<sub>2A</sub> receptor antagonism with MDL100907 reduced the self-administration of (+)MDMA and (–)MDMA in monkeys (Fantegrossi *et al.*, 2002).

#### 5-HT<sub>2B</sub> receptor

A recent study that reported an essential involvement of 5-HT<sub>2B</sub> receptors in the MDMA-induced increase

in extracellular 5-HT levels in the Nac and VTA also reported an essential requirement for these receptors for the hyperlocomotor effects of acute MDMA treatment in mice. This study showed that a selective 5-HT<sub>2B</sub> receptor antagonist RS 127445 blocked the hyperlocomotor effects of MDMA dose-dependently, while MDMA had no hyperlocomotor effects in 5-HT<sub>2B</sub> receptor (–/–) knock-out mice (Doly *et al.*, 2008). In rats, however, the unselective 5-HT<sub>2B/2C</sub> receptor antagonist SB-206553 did not affect MDMA-induced hyperlocomotion (Ball and Rebec, 2005).

#### *5-HT<sub>2C</sub> receptor*

The 5-HT<sub>2C</sub> receptor antagonist SB242084 potentiated MDMA-induced hyperlocomotion in rats (Fletcher *et al.*, 2006). This confirmed an earlier study in rats that used more unselective receptor ligands (Bankson and Cunningham, 2002), together suggesting an inhibitory role for the 5-HT<sub>2C</sub> receptor in MDMA-induced hyperlocomotion. Local application of the 5-HT<sub>2C</sub> receptor agonist MK212 into the mPFC blocked the expression of MDMA-induced sensitization, while the antagonist RS 102221 had no effect (Ramos *et al.*, 2005).

#### *5-HT<sub>3</sub> receptor*

As other psychostimulant drugs do, MDMA induces a profound CPP in rodents (Tzschentke, 2007). The establishment of MDMA-induced CPP could be blocked in rats by pre-treatment with the 5-HT<sub>3</sub> receptor antagonists MDL 72222 and tropisetron (Bilsky and Reid, 1991; Braida *et al.*, 2005).

### **Human studies**

Systematic studies in humans showed that MDMA significantly enhances mood, characterized by the feeling of happiness, euphoria, and sometimes mania-like experience. It also increases wellbeing and extroversion. MDMA leads to a moderate derealization, depersonalization and intensified sensory perception (Peroutka *et al.*, 1988; Vollenweider *et al.*, 1998). A case study in four ecstasy users suggested that the SSRI fluoxetine (p.o.), at a relatively low dose, did not block the reinforcing effects of MDMA (McCann and Ricaurte, 1993). A systematic study in 16 healthy volunteers showed, in contrast, that pre-treatment with the SSRI citalopram (i.v.) could indeed inhibit most of the subjective effects of MDMA. However, citalopram had some side effects, such as fatigue, headache and nausea, which might account for the loss of the effects on mood scales (Liechti *et al.*, 2000a).

The mixed 5-HT<sub>1A/β</sub>-adrenoceptor antagonist pindolol (p.o.) only marginally altered the effects of MDMA on subjective experience in a double-blind, placebo-controlled study in healthy volunteers. Pindolol affected mainly the MDMA effects on the scales 'positive basic mood' and 'mania-like experience', which overall suggests only a minor contribution of 5-HT<sub>1A</sub> receptors to the reinforcing effects of MDMA. In healthy volunteers, the 5-HT<sub>2A/2C</sub> antagonist ketanserin (p.o.) also reduced MDMA-induced changes in perception and emotional excitation, and the acute adverse effects. However, ketanserin had little impact on the positive mood and wellbeing effects of MDMA (Liechti *et al.*, 2000b).

### **The 5-HT system in MDMA addiction**

As an amphetamine derivative, MDMA increases 5-HT activity in the brain after acute application, but also has profound 5-HT neurotoxic effects. Pre-clinical evidence clearly suggests involvement of the 5-HT system in the addiction-related effects of MDMA, but with little focus on core behaviors and with many receptors not investigated. Only 5-HT<sub>2A</sub> and 5-HT<sub>3</sub> receptors were shown to have a facilitatory role in CPP and self-administration, respectively. Based on this pre-clinical knowledge, it might appear hard to design a 5-HT-based pharmacotherapy for MDMA addiction. As for the other psychostimulant drugs, increasing 5-HT levels before drug administration might limit drug effects, but was also found to have some unwanted side effects. For a better treatment design, more basic research into the serotonergic mechanisms of MDMA abuse and addiction is required.

### **Morphine and heroin**

#### ***The neurochemical effects of morphine and heroin on the 5-HT system***

Following the application of opioid drugs of abuse, an increase of extracellular levels of 5-HT is usually observed in *in vivo* microdialysis experiments. The most consistent effects were reported in the dorsal striatum, where an increase of extracellular 5-HT was found (Tao and Auerbach, 1994, 1995; Fadda *et al.*, 2005). In the diencephalon, too, the systemic application of morphine consistently results in the elevation of extracellular 5-HT levels (Grauer *et al.*, 1992; Tao and Auerbach, 1994, 1995; Munn and Borszcz, 2002). For the Nac, an increase of extracellular 5-HT was reported following both systemic (Tao and Auerbach, 1995, 2002; Fadda *et al.*, 2005) as well as local application of morphine

(Tao and Auerbach, 1995). However, this neurochemical effect seems to be modulated by genetic factors, as in one study a decrease of 5-HT in the nucleus accumbens was found in DBA/2J mice, but an increase of 5-HT activity was evident in CB57BL/6J mice (Fadda *et al.*, 2005). Mixed results were obtained when measurements of 5-HT were taken in the mPFC. While both Sudakov *et al.* (2007) and Tao and Auerbach (1995) reported an increase of 5-HT induced by self-administration or systemic application of morphine, respectively, Bland *et al.* (2003) found such a morphine response only in animals that had been exposed to inescapable stress. For the hippocampus, the available results suggest a differentiation between its dorsal and ventral part. Thus, a morphine-induced increase of extracellular 5-HT was found in the ventral hippocampus (Tao and Auerbach, 1994, 1995), while no effect was seen in the dorsal hippocampus (Tao and Auerbach, 1995). Increases of 5-HT were also seen in the amygdala and hypothalamus, while in the medial septum no effects were evident following systemic or local application of morphine (Tao and Auerbach, 1995). Furthermore, an increase of 5-HT activity following morphine could be observed in the rostromedial medulla (Taylor and Basbaum, 2003). For the cell nucleus region of the serotonergic system there seems to be a dissociation between the DRN and MRN regarding the neurochemical effects of morphine. While morphine induced an increase of extracellular 5-HT in the DRN following systemic (Tao and Auerbach, 1995, 2002) or local (Tao and Auerbach, 1995) application, no effects could be found in the MRN (Tao and Auerbach, 1995).

Continuous delivery of morphine via subcutaneously implanted morphine pellets was associated with up-regulation of 5-HT<sub>2</sub> receptors and no change in 5-HT<sub>1</sub> receptors in the cortex, whereas the withdrawal of morphine by removal of these pellets induced up-regulation of 5-HT<sub>1</sub> receptors and no change in 5-HT<sub>2</sub> receptors (Gulati and Bhargava, 1988). The findings regarding the 5-HT<sub>2</sub> receptors were confirmed by a subsequent study in which increased 5-HT<sub>2</sub> receptor binding was evident in the amygdala, midbrain and brainstem of rats with implanted morphine pellets (Gulati and Bhargava, 1989). A study with a 5-HT<sub>1A</sub> selective ligand found down-regulation of these receptors in the hypothalamus, while no effects were found in limbic brain areas, the cortex, the brainstem, the midbrain or the spinal cord (Gulati and Bhargava, 1990).

Chronic morphine treatment was also found to enhance the stimulatory effect of morphine on 5-HT synthesis, and the inhibitory effect of a 5-HT<sub>1A</sub> receptor agonist on 5-HT synthesis, indicating the development of super-sensitivity of somatic 5-HT autoreceptors during morphine-dependence (Sastre-Coll *et al.*, 2002).

This finding corroborated previous results reporting an enhanced hypothermic response to a 5-HT<sub>1A</sub> receptor agonist during morphine withdrawal (Gulati and Bhargava, 1990).

Withdrawal following chronic consumption of a morphine solution resulted in a decrease of 5-HT turnover rates (Ahtee *et al.*, 1989). Furthermore, a challenge injection of morphine following 1 day of withdrawal elicited an attenuated increase of extracellular 5-HT in the DRN. A decrease of 5-HT in the DRN was found following naloxone-precipitated withdrawal (Tao *et al.*, 1998).

### *Reducing and potentiating 5-HT activity*

Morphine-induced hyperactivity and sensitization of the behavioral response following repeated treatment with morphine were blocked by the SSRI fluoxetine (Sills and Fletcher, 1997), suggesting an inhibitory role of 5-HT.

The effectiveness of morphine as a discriminative stimulus was not influenced by pre-treatment with a 5-HT-synthesis inhibitor or an unspecific 5-HT receptor antagonist (Winter, 1977). No effects could be found on the discriminative stimulus properties of heroin or morphine following application of the 5-HT releaser dexfenfluramine or the SSRI fluoxetine (Hynes *et al.*, 1985; Higgins *et al.*, 1993). Fluoxetine also did not substitute for morphine (Platt *et al.*, 1999).

Opiate drugs induce a profound CPP in animals (Tzschentke, 2007). Morphine-induced CPP was attenuated following depletion of 5-HT from the Nac (Spyraki *et al.*, 1988). Both the acquisition (Subhan *et al.*, 2000) and the expression (Maleki *et al.*, 2008) of morphine-induced CPP were enhanced by the application of SSRIs. Contrasting findings were reported when zimelidine was co-administered during the acquisition of morphine-induced CPP, as no effects of the 5-HT uptake blocker were evident (Kruszewska *et al.*, 1986). However, recent findings support an inhibitory role of elevated 5-HT levels on CPP, as the application of fluoxetine or the 5-HT precursor 5-hydroxytryptophan (5-HTP) in morphine-trained rats blocked the expression of morphine-induced CPP. This effect was mimicked by local application of fluoxetine into the Nac (Harris and Aston-Jones, 2001). Notably, this effect was reversed when animals that were not trained on morphine were treated with systemic fluoxetine – i.e., CPP for a morphine-paired environment was enhanced (Harris and Aston-Jones, 2001).

Intravenous self-administration of morphine was enhanced after 5,7-DHT lesions of the Nac (Smith *et al.*, 1987). The self-administration of heroin was reduced by dexfenfluramine (Higgins *et al.*, 1993, 1994; Wang *et al.*, 1995).

5,7-DHT lesions of the DRN and MRN did not have effects on spontaneous or naloxone-precipitated withdrawal (Caillé *et al.*, 2002). The inhibition of 5-HT synthesis was also reported to have only minor effects on morphine withdrawal (Berthold *et al.*, 1989), but unspecific 5-HT receptor antagonists were reported to attenuate symptoms induced by naloxone-precipitated withdrawal (el-Kadi and Sharif, 1995). Moreover, the global increase in 5-HT levels with the application of SSRIs was effective in attenuating the signs of opiate withdrawal induced by naloxone (Gray, 2002; Singh *et al.*, 2003) and by spontaneous morphine withdrawal (Harris and Aston-Jones, 2001).

### 5-HT receptors

#### 5-HT<sub>1</sub> receptors

The discriminative stimulus properties of morphine were attenuated by a selective 5-HT<sub>1A</sub> receptor agonist, but not by a partial 5-HT<sub>1A</sub> agonist (Powell *et al.*, 1994). Agonism of the 5-HT<sub>1A</sub> receptor was found to impair acquisition of morphine-induced CPP (Colpaert *et al.*, 2006). After infusion into the DRN, it also blocked the stress-induced potentiation of morphine-induced CPP (Will *et al.*, 2004). 5-HT<sub>1</sub> receptors seem to play a role in morphine withdrawal, as agonists of the 5-HT<sub>1A</sub> and the 5-HT<sub>1B</sub> receptor were shown to reduce signs of naloxone-induced withdrawal in morphine-dependent mice (Berthold *et al.*, 1989).

#### 5-HT<sub>2</sub> receptors

Locomotor activity evoked by morphine was attenuated by the application of a 5-HT<sub>2A</sub> receptor antagonist (Auclair *et al.*, 2004), while a 5-HT<sub>2C</sub> receptor antagonist had the opposite effect and potentiated morphine-induced hyperactivity (Fletcher *et al.*, 2006). The systemic application of an unselective 5-HT<sub>2</sub> receptor antagonist reduced the acquisition of morphine-induced CPP (Nomikos and Spyraiki, 1988). Involvement of 5-HT<sub>2</sub> receptors in opiate withdrawal was suggested by the finding that naloxone-precipitated morphine withdrawal was attenuated by non-selective 5-HT<sub>2</sub> receptor antagonists (Neal and Sparber, 1986a, b).

#### 5-HT<sub>3</sub> receptor

Morphine-evoked hyperactivity is attenuated by blocking 5-HT<sub>3</sub> receptors (Pei *et al.*, 1993). The discriminative stimulus properties of morphine, however, were not influenced by treatment with 5-HT<sub>3</sub> receptor antagonists (Joharchi *et al.*, 1993). Morphine-induced CPP was blocked by application of 5-HT<sub>3</sub> antagonists during

the conditioning phase (Carboni *et al.*, 1989; Higgins *et al.*, 1992; Bisaga *et al.*, 1993). Application of the 5-HT<sub>3</sub> receptor antagonist ondansetron reduced oral self-administration of morphine when administered chronically, but not following acute application (Hui *et al.*, 1993). No effects of ondansetron on the intravenous self-administration of heroin were evident (Higgins *et al.*, 1994). Also, the 5-HT<sub>3</sub> receptor antagonists MDL 72222 and tropisetron did not influence morphine or heroin self-administration (Hui *et al.*, 1993; Higgins *et al.*, 1994). Tropisetron, however, reduced the preference for a morphine solution (Hui *et al.*, 1993).

There is evidence of involvement of 5-HT<sub>3</sub> receptors in opiate withdrawal. It was reported that application of a 5-HT<sub>3</sub> receptor antagonist attenuated the morphine-withdrawal syndrome induced by a naloxone injection given to morphine-dependent animals (Roychoudhury and Kulkarni, 1996; Pinelli *et al.*, 1997). However, no effects on naloxone-precipitated withdrawal were found when rats were made dependent on morphine by the implantation of morphine pellets. Ondansetron and MDL 72222 were still able to counteract the CPA induced by an injection of a low dose of naloxone to morphine-dependent rats (Higgins *et al.*, 1991).

#### 5-HT<sub>4</sub> receptor

Regarding the role of 5-HT<sub>4</sub> receptors, there is only one study, applying an antagonist with affinity for 5-HT<sub>4</sub> and 5-HT<sub>3</sub> receptors, which led to a reduction of morphine-induced CPP (Bisaga *et al.*, 1993). However, due to the established role of 5-HT<sub>3</sub> receptors in morphine-induced CPP, further studies, using selective ligands at the 5-HT<sub>4</sub> receptor, are needed.

### Human studies

Studies analyzing the association between polymorphisms at the 5-HT transporter gene and opiate addiction reported mixed results. One study in Asian subjects did not find evidence supporting an association between addiction to opiates and polymorphisms of the serotonin transporter gene (Li *et al.*, 2002), but another study did find such an association in Asian subjects (Tan *et al.*, 1999). The same was the case when Caucasian subjects were investigated: while one study found an association with a 5-HT transporter gene polymorphism (Gerra *et al.*, 2004), another did not (Kotler *et al.*, 1999). In addition to ethnic diversity, small sample size or different sample selection across the studies may underlie these conflicting results. Further evidence for involvement of serotonergic genes in heroin dependence has been provided by Nielsen *et al.*

(2008), who reported an association of genetic variations of an enzyme catalyzing serotonin synthesis, tryptophan hydroxylase 1 (TPH1), with heroin dependence in Hispanics, and a haplotype of TPH2 in African-American individuals. Also, an association between heroin dependence and a polymorphism of the 5-HT<sub>2A</sub> receptor gene was reported (Sáiz *et al.*, 2008) and awaits replication. An association between a polymorphism of the 5-HT<sub>1B</sub> receptor gene and a protective effect from heroin addiction was suggested for a Caucasian population (Proudnikov *et al.*, 2006).

The partial 5-HT<sub>1A</sub> receptor agonist buspirone was effective in reducing the subjective and objective signs of opiate withdrawal (Rose *et al.*, 2003). Treatment of opiate addicts with a 5-HT uptake inhibitor resulted in a greater probability of being abstinent only when they lived in a non-adverse environment (Carpenter *et al.*, 2004). Adjunct therapy with a 5-HT uptake inhibitor enhanced the effectiveness of naltrexone treatment in heroin-addicted patients (Landabaso *et al.*, 1998). Fluoxetine was also shown to be effective in the treatment of premature ejaculation after opioid detoxification (Abdollahian *et al.*, 2006).

### 5-HT in morphine and heroin addiction

Several studies reported a genetic predisposition to opiate addiction in humans, which is located in genes coding for parts of the 5-HT system. Unfortunately, the replication rate for these findings is somewhat disappointing and does not yet allow sound conclusions. In general, the application of opiates leads to an increase of 5-HT in certain brain areas. Interestingly, pharmacologically increased 5-HT activity in the brain also attenuated opiate addiction-related behaviors with some success in a clinical setting. Receptor research showed a predominantly inhibitory role for 5-HT<sub>1A</sub> receptors and a mainly facilitatory role for 5-HT<sub>3</sub> receptors in opiate-addiction-related behaviors. However, further studies are needed that investigate the role of other 5-HT receptors, and apply local manipulations to account for the specificity of the functions of local 5-HT in different brain areas.

## Nicotine

### The neurochemical effects of nicotine on the 5-HT system

The effects of nicotine on extracellular levels of 5-HT are not consistent. Following the systemic application of nicotine, there is usually an increase of 5-HT in the FC (Ribeiro *et al.*, 1993; Summers and Giacobini, 1995;

Rossi *et al.*, 2005; Liang *et al.*, 2008), but a lack of effect has also been reported (Singer *et al.*, 2004). An increase of 5-HT levels in the FC could be also induced by local application of nicotine (Toth *et al.*, 1992), but again in one study no effect was reported, although this may have been due to the low nicotine concentration applied (Shearman *et al.*, 2005). Systemic nicotine also increases 5-HT in the medial temporal cortex and the VTA (Singer *et al.*, 2004; Rossi *et al.*, 2005), whereas local administration of a low dose of nicotine had no effect in the medial temporal cortex and decreased 5-HT levels in the VTA (Shearman *et al.*, 2005). In the Nac, an increase in extracellular 5-HT was evident following systemic administration of nicotine (Schiffer *et al.*, 2001; Liang *et al.*, 2008). For the dorsal hippocampus, both an increase (Singer *et al.*, 2004) and a decrease (Rossi *et al.*, 2005) in extracellular 5-HT levels were reported. The latter result was replicated with the local application of nicotine through the microdialysis probe (Shearman *et al.*, 2005). In the ventral hippocampus, nicotine either had no effect (Singer *et al.*, 2004) or decreased 5-HT levels (Rossi *et al.*, 2005). The same occurred when nicotine was applied locally to the ventral hippocampus. There was either no effect (Toth *et al.*, 1992) or a decrease in 5-HT levels (Shearman *et al.*, 2005). Furthermore, locally administered nicotine increased 5-HT in the basolateral amygdala (Shearman *et al.*, 2005), the lateral hypothalamus (Yang *et al.*, 1999) and the DRN (Ma *et al.*, 2005). No effects were evident in the dorsal striatum, the SN, the cerebellum and the pontine nucleus (Toth *et al.*, 1992).

Studies on the serotonergic mechanisms of nicotine withdrawal indicate that chronic application of nicotine may enhance the sensitivity of the serotonin system. For example, an increase of the sensitivity of 5-HT<sub>1A</sub> autoreceptors in the DRN was reported after 2 days of withdrawal (Rasmussen and Czachura, 1997). Consistent with this finding, increased sensitivity of DRN neurons to the application of the SSRI citalopram could be observed 48 hours after chronic nicotine treatment (Touiki *et al.*, 2008). However, there was no effect of nicotine withdrawal on serotonin transporter mRNA expression in the DRN (Semba and Wakuta, 2008). Also, no alterations in 5-HT<sub>1A</sub> receptor mRNA could be found during nicotine withdrawal in the cortex, hippocampus or lateral septum (Kenny *et al.*, 2001).

Repeated injections with nicotine were found to enhance the behavioral response to a 5-HT<sub>2</sub> receptor agonist between 24 hours and 24 days after discontinuation of nicotine treatment (Suemaru *et al.*, 2001; Yasuda *et al.*, 2002), indicating the sensitization of 5-HT<sub>2</sub> receptors during nicotine withdrawal. Opposing findings were reported during early nicotine withdrawal (16–18 hours after the last injection), where down-regulation of 5-HT<sub>2A</sub>

receptors in the cortex (Hayslett and Tizabi, 2005) was evident. Accordingly, both chronic and acute treatment with nicotine attenuated the response to 5-HT<sub>2</sub> receptor stimulation when there was no withdrawal phase before the application of the 5-HT<sub>2</sub> receptor agonist (Tizabi *et al.*, 2001).

### ***Reducing and potentiating 5-HT activity***

Global 5-HT depletion was shown to promote sensitization of the locomotor response to nicotine (Olausson *et al.*, 2001b). Correspondingly, co-administration of nicotine and the SSRI citalopram blocked the expression of behavioral sensitization to nicotine (Olausson *et al.*, 1999). No effect on the discriminative stimulus properties of nicotine was found following the application of a non-specific 5-HT receptor antagonist (Stolerman *et al.*, 1983) or a 5-HT releaser (Mansbach *et al.*, 1998). Elevation of brain 5-HT levels also blocked the dysphoric component of nicotine withdrawal as measured by the reduction of brain-stimulation reward thresholds, without affecting the somatic signs of nicotine withdrawal (Harrison *et al.*, 2001).

### ***5-HT receptors***

#### ***5-HT<sub>1A</sub> receptors***

There is evidence indicating involvement of 5-HT<sub>1A</sub> receptors in the long-term behavioral effects of nicotine. Thus, it was found that the enhancement of the auditory startle response following withdrawal from nicotine was blocked by the application of 5-HT<sub>1A</sub> receptor antagonists (Rasmussen *et al.*, 1997, 2000). Furthermore, behavioral disinhibition on the elevated plus maze following repeated nicotine treatment was counteracted by 5-HT<sub>1A</sub> receptor stimulation (Olausson *et al.*, 2001b).

#### ***5-HT<sub>2</sub> receptors***

There are a number of studies suggesting a role for 5-HT<sub>2</sub> receptors in nicotine-induced locomotion and reward. The acute locomotor effects of nicotine were attenuated by selective stimulation of 5-HT<sub>2C</sub> receptors (Grottick *et al.*, 2001). Pharmacological antagonism of these receptors potentiated the locomotor effects of nicotine (Fletcher *et al.*, 2006). The sensitization of nicotine-induced locomotion was blocked by the administration of an unselective 5-HT<sub>2</sub> receptor agonist (Olausson *et al.*, 2001a) or a selective 5-HT<sub>2C</sub> receptor agonist (Grottick *et al.*, 2001). A role for 5-HT<sub>2</sub> receptors in the mediation of nicotine's

effects is corroborated by experiments testing the effects of 5-HT<sub>2</sub> receptor agonists on the discriminative stimulus properties of nicotine. Thus, drugs activating 5-HT<sub>2A/2C</sub> receptors as well as drugs selectively activating 5-HT<sub>2C</sub> receptors reduced nicotine-lever responding in operant tasks (Batman *et al.*, 2005; Quarta *et al.*, 2007; Zaniewska *et al.*, 2007). 5-HT<sub>2C</sub> receptor agonism did not substitute for nicotine (Quarta *et al.*, 2007). Nicotine-induced CPP was attenuated by 5-HT<sub>2C</sub> receptor agonists (Ji *et al.*, 2006; Hayes *et al.*, 2008). The unselective 5-HT<sub>2</sub> receptor antagonist ketanserin was reported to reduce intravenous nicotine self-administration (Levin *et al.*, 2009). Also, selective stimulation of the 5-HT<sub>2C</sub> receptor reduced nicotine self-administration (Grottick *et al.*, 2001). Altogether, 5-HT<sub>2C</sub> receptor activation reliably reduces virtually all nicotine-addiction related behaviors tested so far.

#### ***5-HT<sub>3</sub> receptor***

5-HT<sub>3</sub> receptors do not seem to play a role in the mediation of the acute locomotor effects of nicotine, as the administration of 5-HT<sub>3</sub> receptor antagonists did not block nicotine-induced hyperactivity (Corrigall and Coen, 1994; Arnold *et al.*, 1995). Antagonists at the 5-HT<sub>3</sub> receptor were found to block nicotine-induced CPP (Carboni *et al.*, 1988, 1989). In contrast, neither intravenous nicotine self-administration (Corrigall and Coen, 1994) nor the effects of nicotine on intracranial self-stimulation (Ivanova and Greenshaw, 1997) were influenced by 5-HT<sub>3</sub> receptor antagonists.

Withdrawal from chronic nicotine treatment induces behavioral depression, which was attenuated by the co-administration of a 5-HT<sub>3</sub> receptor antagonist (Costall *et al.*, 1990a). This effect could be replicated by direct injection of ondansetron into the amygdala or the DRN, but not by injection of the 5-HT<sub>3</sub> receptor antagonist into the MRN, Nac or dorsal striatum (Costall *et al.*, 1990b). Furthermore, the CPA caused by application of the nicotinic receptor antagonist mecamylamine to animals that had been chronically treated with nicotine was attenuated by pre-treatment with the 5-HT<sub>3</sub> receptor antagonist ondansetron (Suzuki *et al.*, 1997).

#### ***5-HT<sub>4</sub> and 5-HT<sub>6</sub> receptor***

The 5-HT<sub>4</sub> receptor does not seem to be involved in the acute hyperlocomotor effects of nicotine (Reavill *et al.*, 1998). Antagonism of 5-HT<sub>6</sub> receptors potentiated the discriminative stimulus effects of nicotine and also the locomotor effects of this drug (Young *et al.*, 2006b). However, further studies are needed to confirm the role of these receptors in the mediation of nicotine's effects.

### Human studies

A study testing the relationship between tryptophan hydroxylase gene polymorphisms and smoking behavior did not find associations between gene variants and smoking status, but rather an association between genotype and the age of smoking initiation, indicating a non-specific genetic effect (Lerman *et al.*, 2001). Concerning the role of 5-HT transporter gene polymorphism, contrasting results have been published. One study did not find an association between 5-HT transporter polymorphism and smoking behavior or abstinence from smoking (Brody *et al.*, 2005), while another report did suggest an association with motives for smoking and nicotine dependence (Lerman *et al.*, 2000).

Mixed results were obtained when serotonergic drugs were used as a treatment of nicotine addiction. Treatment with the SSRI sertraline, in combination with the partial 5-HT<sub>1A</sub> receptor agonist buspirone, increased abstinence from smoking (Carrao *et al.*, 2007). When the SSRI fluoxetine was used as pharmacological treatment to support smoking cessation, no effect on nicotine abstinence was evident, irrespective whether the treated subjects had a history of a depressive disorder or not (Saules *et al.*, 2004). In this study, there were only beneficial effects on weight gain following discontinuation of smoking (Saules *et al.*, 2004). This was consistent with other studies using drugs increasing serotonergic neurotransmission (Spring *et al.*, 1991, 1995). These results support an earlier study which applied the SSRI sertraline as treatment, and did not find effects on abstinence from nicotine (Covey *et al.*, 2002). However, sertraline did reduce withdrawal symptoms (Covey *et al.*, 2002). In contrast to the above reports, a multicenter study in which the effects of fluoxetine treatment applied in addition to behavioral therapy were investigated found positive effects of the SSRI on abstinence rates (Niaura *et al.*, 2002). When tested in patients with depression, paroxetine was effective in reducing cigarette consumption (Miyamoto *et al.*, 2007); however, in another study in depressive smokers it was shown that treatment with fluoxetine only initially reduced smoking, but 6 months after discontinuation of smoking the probability of relapse was higher in the treatment-group (Spring *et al.*, 2007). The selective 5-HT<sub>3</sub> receptor antagonist ondansetron was also tested for its potential to support smoking cessation, but did not prove to be effective (Cropp and Goraharper, 1995; West and Hajek, 1996).

### The 5-HT system in nicotine addiction

The effects of nicotine on 5-HT levels in the brain are complex, and seem to depend on the specific brain area. The relatively scarce pre-clinical evidence suggests that a

general enrichment of 5-HT in the brain might also limit nicotine addiction-related behaviors. Some clinical trials with SSRIs already support this view when short-term success is considered. In the long run the SSRI treatment might increase relapse risk, one element of addiction that is not sufficiently covered by animal studies. At single receptor level there is accumulating evidence for an inhibitory role of 5-HT<sub>2C</sub> receptors in many nicotine-addiction related behaviors in animals. There is also some evidence for an inhibitory role of the 5-HT<sub>6</sub> and a facilitating role of the 5-HT<sub>3</sub> receptors. However, 5-HT<sub>3</sub> receptor antagonism did not prove to be an effective treatment strategy in human smokers. Many other 5-HT receptors still await investigation for their role in nicotine addiction. Given the indications that serotonergic drugs may have some efficacy in supporting discontinuation of smoking, it may be of interest to discover whether genetic polymorphisms within the 5-HT<sub>2C</sub> receptor gene and other components of the 5-HT system contribute to the development and maintenance of nicotine addiction and/or influence the efficacy of the pharmacotherapy of nicotine addiction.

### Conclusion

All of the discussed drugs have a strong effect on 5-HT activity in the brain, either by direct interaction with components of the 5-HT system (cocaine and psychostimulants) or by indirect interaction via other transmitter systems (opiates, nicotine). Early addiction research has tried to link acute and chronic neurochemical effects causally to the observed behavioral effects in a 'proactive way' – i.e., assuming that the increase in neurochemical activity is indeed triggering behavior. As research on the relevance of the 5-HT increase for addiction-related behaviors developed, it became obvious that the 5-HT increase does not uniformly have such a proactive effect, but might rather (or in addition) serve a 'counteractive function' and thus limit the expression of behavior, which is driven by other neurochemical effects of the drug (e.g., by DA and glutamate). At the current state of knowledge, it may well be that some of the 5-HT responses are 'neurochemical epiphenomena' – i.e., they are without any causal effect on addiction-related behavior. A predominant counteractive function is suggested by the well-supported observation that an induced increase in 5-HT extracellular activity prior to addiction-related behavior (e.g., by and SSRI) almost uniformly attenuates subsequent drug-related behaviors for virtually all of the reviewed drugs in this chapter. Complementary to this, a reduction in 5-HT activity can enhance these behaviors. However, a number of studies have shown that for the full expression of addiction-related behaviors, the ratio of the 5-HT and DA

activation is important. Therefore, single manipulation of the 5-HT activity might serve as a potential therapeutic intervention, but may mask the real function of 5-HT in drug addiction. A better view can possibly be obtained when looking at the contribution of single receptors. Given the large number of different 5-HT receptors and their splice variants, it may not be surprising that these receptors play very different roles for normal as well as addiction-related behavior. These multiple functional dissociations are taken to another level of complexity when local receptor populations are considered. A great number of studies revealed that one 5-HT receptor can have very different effects on addiction-related (and normal) behavior depending on its brain area, cell type and synaptic localization (Müller and Huston, 2006). Thus, some receptor populations did appear to have proactive effects (i.e., are translating the drug-induced 5-HT increase into addiction-related behaviors) while others counteracted them, or were not involved at all. While acknowledging this complexity will be important in understanding the 5-HT role in drug addiction, it might also obscure the use of 5-HT system's components for addiction pharmacotherapy in humans. So far, serotonergic approaches alone and in combination with other, non-pharmacological therapies have not proved successful in the long term. However, there are new targets emerging, such as the 5-HT<sub>2C</sub> receptor, for which the search for a suitable intervention has started. Possibly, personalized treatment approaches using, for example, 5-HT system gene polymorphisms as biological markers might also enhance the use of the 5-HT system to treat drug addiction in the future.

# The Serotonergic System in Obsessive-Compulsive Disorder

Addy van Dijk, Andre Klompmakers and Damiaan Denys\*

*Department of Psychiatry, Academic Medical Center, University of Amsterdam, Amsterdam, The Netherlands*

**Abstract:** Obsessive-compulsive disorder (OCD) is a psychiatric disorder consisting of obsessions and compulsions. Over the past two decades it has been suggested that OCD might be related to the functioning of brain serotonin systems, mainly because of the anti-obsessional efficacy of selective serotonin reuptake inhibitors (SSRIs). Though the efficacy of SSRIs suggests a role of the serotonergic system in OCD, the exact function of serotonin (5-HT) is still unclear. Is the serotonergic system implicated in the pathophysiology of OCD, or is it implicated in the treatment effect in OCD? Do SSRIs compensate for a fundamental abnormality of the serotonergic system, or do SSRIs modulate an intact serotonergic system to compensate for another neurotransmitter mechanism? This chapter reviews five lines of evidence that have been cited in support of the 5-HT hypothesis: (1) pharmacotherapy; (2) pharmacologic challenge studies; (3) receptor binding studies; (4) genetic association studies; and (5) animal models.

**Keywords:** obsessive-compulsive disorder, anxiety disorder, pharmacotherapy, neurobiology, serotonin, dopamine.

## Introduction

Obsessive-compulsive disorder (OCD) is a psychiatric disorder which consists of obsessions and compulsions. Obsessions are unwanted ideas or impulses that repeatedly well up in the mind, such as persistent fears to harm a loved one, an unreasonable concern with becoming contaminated or an excessive need to do things correctly or perfectly. Compulsions are repetitive behaviors or rituals such as washing and checking, counting, mentally repeating phrases, list-making or endlessly rearranging objects.

Over the past two decades it has been suggested that OCD might be related to the functioning of brain serotonin systems, mainly because of the anti-obsessional efficacy of SSRIs. The 5-HT hypothesis originated from the observed efficacy of SSRIs in OCD, compared to inefficacy of selective noradrenergic and dopaminergic reuptake inhibitors, suggesting a specific abnormality of the serotonergic system in OCD (Baumgarten and Grozdanovic, 1998). However, the exact function of serotonin (5-HT) in OCD is still unclear. This chapter provides an overview of the evidence supporting a role for the serotonergic system in OCD. It reviews five lines of evidence that have been cited in support of the 5-HT

hypothesis: (1) pharmacotherapeutic studies; (2) pharmacotherapy; (3) receptor binding studies; (4) genetic association studies; and (5) animal models.

## Pharmacotherapy

A common method to unravel the pathophysiology of a disorder in psychiatry is to study the mechanism of action of effective drug therapy. The cornerstone of pharmacotherapy for OCD is serotonin reuptake inhibition, either with clomipramine or with selective serotonin reuptake inhibitors. Over the past 25 years, a number of double-blind, randomized, placebo controlled studies in OCD have confirmed the efficacy of clomipramine and the selective serotonin reuptake inhibitors fluvoxamine, paroxetine, sertraline, fluoxetine and citalopram. Efficacy of drug trials in OCD is commonly expressed in absolute changes of Yale-Brown Obsessive-Compulsive Scale (Y-BOCS) scores. The Y-BOCS is a clinician rated 10-item scale with a total range of 0 to 40 that measures severity of obsessions and compulsions (Goodman *et al.*, 1989a, b). In many cases, patients are classified as responders when their scores on the Y-BOCS decrease by 25–35 percent.

The efficacy of clomipramine was established in more than 10 placebo-controlled trials. In a recent meta-analysis, clomipramine shows a net improvement (difference) compared with placebo of 8.20 points on the Y-BOCS

\*Corresponding author  
E-mail: d.denys@amc.nl

(Ackerman and Greenland, 2002). Responder rates to clomipramine vary between 40 and 50 percent of patients. Though in some cases low doses of clomipramine over a short period of time may result in significant improvement of symptoms, clomipramine treatment should last at least 10–12 weeks with a dose of 250–300mg/day to demonstrate a full effect. Clomipramine has never been tested in a controlled fixed-dose study to assess optimal doses. Fluvoxamine was superior to placebo in four placebo-controlled trials and equipotent to clomipramine in five comparison trials (Dell'osso *et al.*, 2005). The pooled difference of fluvoxamine compared with placebo in these trials was 4.8 points on the Y-BOCS. Fluvoxamine has never been examined in a fixed-dose trial, but appears to be efficacious from 150 to 300mg/day. Fluoxetine was effective in three placebo-controlled trials and equipotent to clomipramine in two comparison trials. The pooled difference on the Y-BOCS of fluoxetine compared with placebo was 1.6 points (Ackerman and Greenland, 2002). Responder rates to fluoxetine vary between 25 and 30 percent of patients. Sertraline was effective in four placebo-controlled trials and equipotent to clomipramine in one comparison trial. The pooled difference of sertraline compared with placebo in these trials was 2.5 points on the Y-BOCS (Ackerman and Greenland, 2002). Although no correlation was found of sertraline plasma levels with treatment outcome, in a large multicenter trial, sertraline 50mg/day and 200mg/day were superior to placebo, whereas 100mg/day was not.

For a long time, paroxetine was shown to be effective in just one published placebo-controlled trial and equipotent to clomipramine in the same trial (Zohar and Judge, 1996; Ackerman and Greenland, 2002; Ninan, 2003). The difference of paroxetine compared with placebo was 3.1 points on the Y-BOCS. Doses of 40 and 60mg/day were significantly better than placebo, whereas 20mg was not. The efficacy of citalopram in OCD was recently established in a placebo-controlled study including 401 patients who were randomized to receive citalopram 20, 40 or 60mg/day or placebo for 12 weeks (Montgomery *et al.*, 2001). The difference of citalopram compared with placebo was 3.6 points on the Y-BOCS. The highest responder rate (65 percent), defined as 25 percent improvement in Y-BOCS entry score, was observed in the 60mg group compared with 52 percent and 57.4 percent in the 40mg and 20mg groups, respectively. Surprisingly, the responder rate on placebo was 36.6 percent with a mean decrease on the Y-BOCS of 5.6 points. This high improvement rate on placebo, uncommon in OCD, has been explained as a result of inclusion of milder, atypical cases, in which spontaneous remission is more frequent. Patients with longer duration of OCD, more severe OCD symptoms or previous SSRI use were less likely to be responders to citalopram, whereas patients who received adequate medication

doses for sufficient periods of time were more likely to be responders (Stein *et al.*, 2001). In a small study, clinical response did not appear to be related to citalopram plasma concentrations (Bareggi *et al.*, 2004).

The efficacy of clomipramine and five SSRIs has been established with placebo-controlled trials, but are clomipramine, fluvoxamine, paroxetine, sertraline, citalopram and fluoxetine equally effective (Soomro *et al.*, 2008)? Meta-analyses using statistical methods to pool samples from different studies may answer this question, offering a precise estimate of the treatment effect from separate drug trials. Consistent with previous meta-analyses, Ackerman and colleagues recently confirmed that clomipramine is more effective than SSRIs in placebo-controlled trials (Ackerman and Greenland, 2002). For seven clomipramine trials the net Y-BOCS decrease compared with placebo was 8.19, whereas for four fluvoxamine trials the net Y-BOCS decrease was 4.84, for three fluoxetine trials 1.61, and for four sertraline trials 2.47. It is worth noting, however, that the largest effect values for clomipramine were found in early studies and have not been as clearly replicated in more recent studies comparing it with SSRIs. Moreover, in the long term, drop-out rates in clomipramine-treated patients are higher than in SSRI-treated patients. In another meta-analysis which included 32 studies covering a total of 3588 OCD patients, again, clomipramine had the largest effect value of 1.55, versus 0.81 for fluoxetine and 1.36 for sertraline (Eddy *et al.*, 2004). This meta-analysis also demonstrated that two-thirds of the patients who completed a medication trial improved. Across all active treatments, the mean Y-BOCS decrease was 7.1, resulting in a mean post-treatment Y-BOCS score of 17.9, whereas for placebo conditions the Y-BOCS decrease was 1.8.

Clearly, in effectiveness, clomipramine is superior to all the SSRIs. In practice, however, the choice of a drug also depends on its side-effect profile and potential for drug interactions. Clomipramine has the greatest anticholinergic side-effect profile, potential cardiotoxicity, and is the most noxious in an overdose. In contrast, SSRIs may be associated with more complaints of headaches, nausea, insomnia or agitation, but are safer and less prone to drug interactions. Considering side effects, toxicity and potential drug interactions, SSRIs are usually the first treatment of choice.

The 5-HT hypothesis of OCD has emerged from the observation that only antidepressants that preferentially block the serotonin transporter (5-HTT) are efficacious in OCD. A comparison of the clinical efficacy of clomipramine, fluvoxamine and sertraline with that of desipramine, an antidepressant that selectively blocks the uptake of norepinephrine, supports the notion that inhibition of the 5-HTT is required for antidepressants to be efficacious in OCD (Zohar and Insel, 1987; Leonard

*et al.*, 1989; Goodman *et al.*, 1990; Hoehn-Saric *et al.*, 2000). Denys and colleagues have shown that venlafaxine and paroxetine are equally efficacious in OCD, suggesting that inhibition of the norepinephrine uptake does not contribute to the effect of antidepressants as well (Denys *et al.*, 2003). As mentioned previously, this finding does not necessarily point to an abnormal serotonergic system in OCD. On the contrary, several observations lend support to the idea that inhibition of the 5-HTT, although required for antidepressants to work in OCD, is not causally related to the genesis of the disorder. First, nearly half of OCD patients do not respond to SSRI treatment (Denys, 2006). Even with adequate treatment, the mean symptom decrease is 30–50 percent at most (Denys *et al.*, 2002). Second, the doses of SSRIs required for treatment of OCD are substantially higher than necessary to completely block the 5-HTT (Kent *et al.*, 2002; Meyer, 2007; Voineskos *et al.*, 2007). Third, depletion studies of tryptophan, necessary for the synthesis of 5-HT, did not show a worsening of symptoms in OCD patients (Berney *et al.*, 2006). Fourth, the therapeutic effects in OCD are usually not seen within 8 weeks of treatment, which is much later than in patients with depression. Fifth, there is no relation between the selectivity and binding potential of the different SSRIs and clinical effect size (Baumgarten and Grodzanovic, 1998).

In conclusion, the 5-HT hypothesis was initially motivated by the observed differential efficacy of SSRIs in alleviating OCD symptoms. However, these findings, although attesting to the therapeutic versatility of serotonin transporter inhibition in OCD, do not necessarily reflect the existence of a neurobiological abnormality in the central serotonergic system in OCD. SSRIs may modulate serotonin via an intact serotonergic system to compensate for the underlying pathogenesis.

### Pharmacologic challenge studies

Another approach to assessing the function of the serotonergic system in OCD is by administration of indirect or direct serotonin receptor agonists or antagonists. Pharmacological challenges with meta-chlorophenylpiperazine (mCPP) have shown to exacerbate obsessive-compulsive (OC) symptoms. mCPP is a non-selective 5-HT receptor agonist acting mainly at the 5-HT<sub>2C</sub> receptors, but with affinity also for the 5-HT<sub>1B/1D</sub> and 5-HT<sub>1A</sub> receptors (Westenberg *et al.*, 2007). Administration of psilocybin, a psychedelic agent with potent 5-HT<sub>2A/2C</sub> and 5-HT<sub>1A</sub> agonist properties, in nine subjects resulted in acute reductions of the Y-BOCS score in a controlled clinical environment (Moreno *et al.*, 2006). A challenge with the selective 5-HT<sub>1A</sub> agonist ipsapirone did not induce exacerbation of OC symptoms in OCD patients (Lesch *et al.*, 1991a, b). Pindolol, on the

other hand, a  $\beta$ -blocker and 5-HT<sub>1A</sub> receptor antagonist, was shown to augment the therapeutic effect of paroxetine by increasing serotonergic transmission (Dannon *et al.*, 2000). Pharmacological challenge studies with 5-HT<sub>1D</sub> receptor agonists in OCD are inconsistent. Some studies show an exacerbation of OC symptoms with sumatriptan, though zolmitriptan, with a better penetration of the blood–brain barrier than sumatriptan, failed to increase OC symptoms (Pian *et al.*, 1998; Stein *et al.*, 1999; Boshuisen and den Boer, 2000; Koran *et al.*, 2001; Gross-Isseroff *et al.*, 2004). Atypical antipsychotics with potent 5-HT<sub>2A</sub> and D<sub>2</sub> antagonistic properties have anti-obsessional qualities in addition to SSRI treatment. Risperidone, an atypical antipsychotic, is the most potent and selective 5-HT<sub>2A</sub> antagonist available to clinicians (Marek *et al.*, 2003). Multiple double-blind studies have found risperidone augmentation of ongoing SSRI treatment in OCD to be effective (McDougle *et al.*, 2000; Hollander *et al.*, 2003; Erzegovesi *et al.*, 2005). Hewlett and colleagues initiated a pilot study with the 5-HT<sub>3A</sub> receptor antagonist ondansetron. They found that of the eight OCD patients, six completed the trial and three subjects achieved a clinically significant response of  $\geq 35$  percent reduction in Y-BOCS score (Hewlett *et al.*, 2003). On the contrary, Broocks and colleagues found that pre-treatment with ondansetron did not affect any of the self-rated behavioral symptoms induced by an mCPP challenge with 11 OCD-patients (Broocks *et al.*, 1998).

In conclusion, pharmacological challenges implicate a role for the 5-HT<sub>2A</sub> receptor and/or 5-HT<sub>2C</sub> receptor, and possibly the 5HT<sub>1B/1D</sub> receptor in the pathophysiology of OCD.

### Receptor binding studies

Neuroimaging with positron emission tomography (PET) or single photon emission computer tomography (SPECT) offers a unique tool to probe the serotonergic system *in vivo*. For a summary of the different receptor binding studies discussed in this review, see Table 1.

#### 5-HTT binding studies at baseline

Pogarell and colleagues reported a 25 percent higher 5-HTT availability in the midbrain region of nine unmedicated OCD patients using the radiotracer [<sup>123</sup>I]-2 $\beta$ -carbomethoxy-3 $\beta$ -(4-iodophenyl)tropane ([<sup>123</sup>I] $\beta$ -CIT) and SPECT imaging (Pogarell *et al.*, 2003). Stratification of the patients according to onset of the disorder revealed that the significant difference was only present in patients with an early age of onset compared to control.

**Table 1** Receptor binding studies

Research group	Transporter, receptor of interest	Patients in study	Results	Y-BOCS (mean)	Co-morbidity	Control groups	Acquisition time (hours)	Radiotracer	Imaging technique
Pogarell <i>et al.</i> , 2003	5-HTT	9, heterogeneous, drug-free (7 drug-naïve)	25% higher 5-HTT availability in the midbrain region	23.0 ± 8.2	Depression	—	24	[ <sup>123</sup> I]β-CIT	SPECT
Stengler-Wenzke <i>et al.</i> , 2004	5-HTT	10, heterogeneous, drug-free	Significant reduction of 5-HTT availability in the midbrain and upper brainstem	30 ± 2.5	—	Age matched	24	[ <sup>123</sup> I]β-CIT	SPECT
Hesse <i>et al.</i> , 2005	5-HTT/DAT	15, heterogeneous, drug-naïve	Reduced availability of striatal DAT and of thalamic/hypothalamic, midbrain and brainstem 5-HTT	25.3 ± 8.8	—	—	24	[ <sup>123</sup> I]β-CIT	SPECT
Zitterl <i>et al.</i> , 2007	5-HTT	24, homogeneous OC-checkers, drug-free	18% reduction in 5-HTT availability in the thalamus and hypothalamus	25.1 ± 5.0	—	Age and gender matched	4	[ <sup>123</sup> I]β-CIT	SPECT
Hasselbalch <i>et al.</i> , 2007	5-HTT	9, heterogeneous, drug-free	13% reduction in midbrain-pons 5-HTT binding	22	Anxiety, depression	—	10 min–7 hours	[ <sup>123</sup> I]β-CIT	SPECT
Reimold <i>et al.</i> , 2007	5-HTT	9, heterogeneous, drug-free	Significant reduction in 5-HTT availability in thalamus and midbrain	21.4 ± 7.7	—	Age matched	0–80 min	[ <sup>11</sup> C]DASB	PET
van der Wee <i>et al.</i> , 2004	5-HTT	15, heterogeneous, psychotropic-naïve	No difference in 5-HTT binding density in the midbrain, thalamus and pons of OCD patients compared to controls	23.4 ± 4.2 (cut off score of 16)	—	Age and gender matched	4	[ <sup>123</sup> I]β-CIT	SPECT
Simpson <i>et al.</i> , 2003	5-HTT	11, heterogeneous, drug-free	No significant difference was found between OCD patients and control subjects	20 ± 4	—	Age and gender matched	130 min	[ <sup>11</sup> C]McN 5652	PET
Stengler-Wenzke <i>et al.</i> , 2006	5-HTT	10, heterogeneous, drug-free at baseline; 5, after 1 year 60-mg citalopram treatment. Patients on stable treatment during 2° scan	The availability of 5-HTT in the thalamus, midbrain and brainstem decreased significantly after treatment with 60 mg citalopram for 1 year	32.0 ± 2.5 (pre-treatment)	—	Age matched	24	[ <sup>123</sup> I]β-CIT	SPECT
Zitterl <i>et al.</i> , 2008	5-HTT	24, OC-checkers, drug-free at baseline; 12-week clomipramine treatment. Patients on stable 150-mg treatment during 2° scan	A 48% reduced brain SERT availability in the thalamus–hypothalamus after 12-week treatment. Significantly negative associations between SERT availability and Y-BOCS both at baseline and after treatment	26.2 ± 4.9 (pre-treatment) 18.9 ± 6.7 (after treatment)	—	—	4	[ <sup>123</sup> I]β-CIT	SPECT

Pogarell <i>et al.</i> , 2005	5-HTT/DAT	2, heterogeneous, drug-naïve; 12 weeks 40-mg citalopram treatment. Patients on stable treatment during 2 <sup>e</sup> scan	A 36.5% decrease in 5-HTT availability after 12 weeks' therapy with 40 mg citalopram. An increase of 40% in the availability of DAT	?	—	No control group	20–24	[ <sup>123</sup> I]β-CIT	SPECT
Kim <i>et al.</i> , 2007	DAT	10, heterogeneous, drug-free; 16-week treatment 73.3 mg fluoxetine ( <i>n</i> = 6) 53.3 mg paroxetine ( <i>n</i> = 3) 250 mg clomipramine ( <i>n</i> = 1). Patients on stable treatment during 2 <sup>e</sup> scan	Decreased DAT binding ratio in the right basal ganglia after treatment with SRIs	33.10 ± 6.38 (pre-treatment)	Depression, tic disorder	No control group	2	[(123)I]IPT	SPECT
Moresco <i>et al.</i> , 2007	D <sub>2</sub>	9, heterogeneous, drug-naïve; 12-week treatment 150–300 mg fluvoxamine. Patients on stable treatment during 2 <sup>e</sup> scan	Significant increase between 6.9 and 9.7% in striatal [(11)C]Rac binding potential after chronic treatment with fluvoxamine; the mean values after treatment were closer to those observed in normal subjects	29 ± 5	—	—	0–60 min	[(11)C]Rac	PET
Adams <i>et al.</i> , 2005	5-HT <sub>2A</sub>	15, heterogeneous, drug-free 12-week treatment 60–80 mg paroxetine 50–150 mg sertraline 60–80 mg fluoxetine 60–80 mg citalopram. Patients on stable treatment during 2 <sup>e</sup> scan	9% higher 5-HT <sub>2A</sub> receptor binding potential in the caudate nucleus before treatment; no significant change after SSRI treatment	30 ± 6.8	Depression, anorexia, anxiety, single phobia	Age and gender matched	90 min	[ <sup>18</sup> F]altanserin	PET
Perani <i>et al.</i> , 2008	5-HT <sub>2A</sub>	9, heterogeneous, drug naïve	Significant reduction of 5-HT <sub>2A</sub> receptor availability in frontal cortex, cingulated cortex, parietal and temporal associative cortices; significant inverse correlation between 5-HT <sub>2A</sub> availability and Y-BOCS	29.44 ± 4.42	—	Age matched	0 min	[ <sup>11</sup> C]MDL-BP	PET

*Abbreviations:* [<sup>123</sup>I]β-CIT, [<sup>123</sup>I]-2β-carbomethoxy-3β-4-iodophenyltropane; SPECT, single photon emission computer tomography; DAT, dopamine transporter; 5-HTT, serotonin transporter; OCD, obsessive-compulsive disorder; PET, positron emission tomography; [(123)I]IPT, iodine-123-labeled N-3-iodopropen-2-yl-2 beta-carbomethoxy-3beta-4-chlorophenyl tropane; [(11)C]Rac, [(11)C]raclopride.

Patients and controls in this study were not matched by age and gender (Pogarell *et al.*, 2003).

In contrast to this finding, Stengler-Wenzke and colleagues described a significant reduction of 5-HTT availability in the midbrain and upper brainstem in 10 drug-free OCD patients compared to age-matched controls. However, they did not report the age of onset of OCD symptoms (Stengler-Wenzke *et al.*, 2004).

In agreement with this, Hesse and colleagues reported a significantly reduced 5-HTT density in the midbrain and the thalamus in 15 drug-naïve OCD patients compared to controls (Hesse *et al.*, 2005). Comparing 24 drug-free OC checkers to controls, Zitterl and colleagues found an 18 percent reduction in 5-HTT availability in the thalamus and hypothalamus. Reduced 5-HTT availability correlated with increased severity of OC symptomatology and short duration of illness, although not with age and age at onset (Zitterl *et al.*, 2007). Hasselbalch and colleagues found a 13 percent reduced midbrain-pons 5-HTT binding in nine drug-free OCD patients. No correlation between 5-HTT binding and any clinical variables (age at onset, disease duration and Y-BOCS score) was shown (Hasselbalch *et al.*, 2007). A [<sup>11</sup>C] DASB PET study reported significantly reduced 5-HTT availability in the thalamus and in the midbrain in nine drug-free OCD patients (Reimold *et al.*, 2007).

Finally, van der Wee and colleagues found no difference in 5-HTT binding density in the midbrain, thalamus and pons of drug-naïve OCD patients compared to controls using [<sup>123</sup>I]β-CIT and SPECT (van der Wee *et al.*, 2004). Simpson and colleagues, using [<sup>11</sup>C]McN 5652 as a radioligand in combination with PET, found no significant difference between OCD patients and control subjects (Simpson *et al.*, 2003).

### 5-HTT binding studies after SSRI treatment

Treatment with 60 mg citalopram for a year in five patients resulted in a decrease of 5-HTT availability in the thalamus, midbrain and brainstem (Stengler-Wenzke *et al.*, 2006). In a group of 24 OC checkers, 12 weeks of treatment with clomipramine resulted in a 48 percent decrease in brain SERT availability in the thalamus-hypothalamus. A significantly negative association between SERT availability and Y-BOCS both at baseline and after treatment was also found in this group of 24 OC checkers (Zitterl *et al.*, 2008). A 12-week period of treatment with 40 mg citalopram in two patients led to a 36.5 percent decrease in 5-HTT availability and an increase of 40 percent in the availability of dopamine transporter (DAT) in the midbrain-pons region (Pogarell *et al.*, 2005). A SPECT study with iodine-123-labeled N-(3-iodopropen-2-yl)-2β-carbomethoxy-3β-(4-chlorophenyl)tropane ([<sup>123</sup>I]IPT)

as radiotracer found a significantly decreased DAT binding ratio in the right basal ganglia after 16 weeks of treatment with SSRIs in 10 drug-free patients (Kim *et al.*, 2007). Moresco and colleagues found, in a PET study with [(11)C]raclopride ([<sup>11</sup>C]Rac) as radiotracer, a slight but significant increase in striatal [(11)C]Rac binding potential, varying from 6.9 percent to 9.7 percent, after a 12-week course of treatment with 150–300 mg fluvoxamine (Moresco *et al.*, 2007).

### 5-HT<sub>2A</sub> receptor binding studies

A PET study with [<sup>18</sup>F]altanserin in naïve OCD patients showed a significantly higher 5-HT<sub>2A</sub> receptor binding potential in the caudate nucleus compared to age- and gender-matched healthy controls. This increase in 5-HT<sub>2A</sub> receptor binding was not influenced by subsequent treatment with SSRIs (Adams *et al.*, 2005). The increased 5-HT<sub>2A</sub> binding density might result from a lack of 5-HT in the basal ganglia. However, a PET study with the radioligand [<sup>11</sup>C]MDL-BP found a significant reduction of 5-HT<sub>2A</sub> receptor availability in frontal cortex and cingulate cortex, as well as in parietal and temporal associative cortices, in drug-naïve OCD patients compared to age-matched controls. The reduced 5-HT<sub>2A</sub> receptor availability in the orbitofrontal and dorsolateral frontal cortex correlated with clinical severity (Perani *et al.*, 2008).

In summary, though some of the neuroimaging studies suggest that an impaired 5-HTT function might play a role in the pathogenesis of OCD, others indicate that successful SSRI treatment is associated with normalization of the dopamine (DA) function. There are mixed results regarding the possible role of the 5-HT<sub>2A</sub> receptor in the neuroimaging studies.

### Genetic association studies

Genetic studies investigating the possible role for polymorphism in the promoter region of the 5-HTT gene (5-HTTPR) have generated conflicting results (Table 2). Some studies reported an association between the S allele of 5-HTTPR and OCD (Denys *et al.*, 2006; Perez *et al.*, 2006; Grados *et al.*, 2007; Lin, 2007). The S allele reduces 5-HTT mRNA expression, and a higher frequency of this allele would suggest a lower density of 5-HTT in OCD patients. Others found an association between the two copies of the long allele (L) in the 5-HTTLPR region and OCD (McDoughle *et al.*, 1998; Bengel *et al.*, 1999). Kim and colleagues investigated the 5-HTTPR polymorphism in association with the phenotypic characteristics of OCD, and found that patients with the L-genotype had

**Table 2** Genetic association studies

Research group	Transporter, receptor of interest	Patients in study	Origin	Results
Grados <i>et al.</i> , 2007	5-HTTPR	149 OCD patients, 397 controls	Caucasians (>90%)	A trend for both the S/s Genotype and the S allele frequency was found
Lin <i>et al.</i> , 2007	5-HTTPR	Meta-analysis of 13 independent case-control association studies 3000 subjects	—	An association between OCD and the SS homozygous genotype was found; it is inversely associated with the LS heterozygous genotype and has no association with the LL homozygous genotype or the allelic distribution was found
Perez <i>et al.</i> , 2006	5-HTTPR	26 OCD patients, 87 controls	Caucasians	A significant association between the S/S genotype and OCD
Denys <i>et al.</i> , 2006	5-HTTPR/ 5-HT <sub>1B</sub> /5-HT <sub>2A</sub>	156 OCD patients, 134 controls	Caucasians	No significant differences in genotype distribution and allele frequency for polymorphisms investigated were found relative to controls; however, there was an indication towards an association of the 5-HTTLPR S allele with female OCD patients, and the 5-HT2A G-allele and GG genotype with patients with a positive family history of OCD and an early onset of disease
Bengel <i>et al.</i> , 1999	5-HTTPR	75 OCD patients, 397 ethnically matched controls	Caucasians	A statistically significant association between the L/L genotype and OCD was found
McDougle <i>et al.</i> , 1998	5-HTTPR	34 family trios	European-Americans	An association between the L allele in the 5-HTTPR region and OCD was found
Kim <i>et al.</i> , 2005	5-HTTPR	124 OCD patients, 171 controls	Koreans	No significant association between OCD and 5-HTTPR was found; however, patients with the L-genotype had higher scores for the religious and somatic obsessions
Cavallini <i>et al.</i> , 2002	5-HTTPR	180 OCD patients, 112 controls	Italians	Patients who were homozygote for the L-allele could more often be classified as symmetry/ordering subtype OCD patients
Denys <i>et al.</i> , 2007	5-HTT, 5-HT <sub>2A</sub>	91 OCD patients	Dutch	The S/L genotype of the 5-HTTLPR polymorphism was amongst the majority of OCD patients who responded with a Y-BOCS decrease of more than 25% to a 12-week treatment period with 300 mg venlafaxine; the G/G genotype of the 5-HT <sub>2A</sub> polymorphism was amongst the majority of OCD patients who were responders to a 12-week treatment period with 60 mg paroxetine
Camarena <i>et al.</i> , 2001	5-HTTPR	115 OCD patients, 136 controls. Family-based design: 43 trios	Mexicans	No significant association between L allele and OCD was found; no preferential transmission of L allele to OCD probands was found
Chabane <i>et al.</i> , 2004	5-HTTPR	Case-control study: 106 OCD patients, 171 controls. Family association study: 116 trios including an OCD patient	French Caucasians	There was no association between the 5-HTTLPR polymorphism and OCD in either the case-control study or the family study
Di Bella <i>et al.</i> , 2002	5-HTTPR	181 OCD patients, 191 controls	Italians	No significant differences in allele/genotype distribution of the 5-HTTLPR was found

(Continued)

**Table 2** (Continued)

Research group	Transporter, receptor of interest	Patients in study	Origin	Results
Dickel <i>et al.</i> , 2007	5-HTTPR/ 5-HT <sub>2A</sub>	21 parent–child trios from singleplex families; 7 parent–child trios from multiplex families; 26 probands with early-onset OCD	Americans	There was no evidence for association detected at any of the polymorphisms in the entire set of subjects
Frisch <i>et al.</i> , 2000	5-HTTPR/ 5-HT <sub>2A</sub> / 5-HT <sub>2C</sub>	75 patients, 172 ethnically matched controls	Jews	There were no statistically significant differences between patients and control for the genotypic and allelic distribution of all polymorphisms tested
Meira-Lima <i>et al.</i> , 2004	5-HTTPR/ 5-HT <sub>2A</sub>	79 OCD patients, 202 controls	Brazilians, Caucasian (90.5%)	A statistically significant difference in the genotypic distribution and in the allelic frequencies for the C516T 5HT <sub>2A</sub> gene polymorphism was found; however, no significant difference for the 5HTTLPR and the T102C 5HT <sub>2A</sub> gene polymorphisms was found
Wendland <i>et al.</i> , 2006	5-HTTPR	279 OCD-probands, 390 controls	Caucasian	Allelic frequencies for G56A did not differ significantly between probands and controls
Saiz <i>et al.</i> , 2008	5-HTTPR/ 5-HT <sub>2A</sub>	99 OCD patients, 56 non-OCD psychiatric patients, 420 controls	Spanish Caucasian	No significant differences were found with respect to 5-HTTLPR and 5-HT <sub>2A</sub> polymorphisms
Mundo <i>et al.</i> , 2002	5-HT <sub>1B/1D</sub>	Family-based design: 121 families, 157 OCD patients	Canadians, Caucasian (96.7%)	A significant association between OCD and the G861 polymorphism of the 5-HT <sub>1D</sub> gene was found; the G-allele was associated with OCD and predicted OC severity
Camarena <i>et al.</i> , 2004	5-HT <sub>1B/1D</sub>	72 trios	Mexicans	No significant association between the G-allele and OCD was found; however, subjects with a preferential transmission of the G861 variant showed higher Y-BOCS obsession scores compared to patients carrying the C861 allele
Levitani <i>et al.</i> , 2006	5-HT <sub>1B/1D</sub>	165 female probands with bulimia nervosa	Canadians	There was no significant association between the G-allele and OCD; the G861C polymorphism did strongly differentiate between full syndrome vs partial syndrome OCD
Di Bella <i>et al.</i> , 2002	5-HT <sub>1B/1D</sub>	Family-based design: 79 trios	Italians	No preferential transmission of either allele of the 5-HT <sub>1D</sub> gene was observed
Enoch <i>et al.</i> , 2001	5-HT <sub>2A</sub>	101 OCD patients, 138 controls	Caucasian	A higher frequency of the –1438G/A allele was found in female OCD patients compared to healthy women; however, there was no difference in allele frequencies between male OCD patients and healthy men
Walitza <i>et al.</i> , 2002	5-HT <sub>2A</sub>	55 OCD patients, 223 controls	Germans	A statistically significant association between the A-allele of the 5-HT <sub>2A</sub> receptor gene with OCD was found
Kim <i>et al.</i> , 2000	5-HT <sub>2B</sub>	7 early-onset probands, 10 autism probands, 10 controls	?	No evidence for functional mutation was found in the sequenced regions of HTR <sub>2B</sub>
Cavallini <i>et al.</i> , 1998	5-HT <sub>2C</sub>	109 OCD patients, 107 controls	Italian	No allelic or genotypic association of OCD with the 5HT <sub>2C</sub> receptor gene mutation was found
Mossner <i>et al.</i> , 2007	5-HT <sub>3A</sub>	Family-based design: ±75 trios	Germans, Caucasian	No evidence for a preferential transmission of either allele of the 5-HT <sub>3A</sub> was found

higher scores for the religious and somatic obsessions (Kim *et al.*, 2005). A principal component analysis on the Y-BOCS checklist performed by Cavallini and colleagues demonstrated that patients who were homozygote for the L-allele more often could be classified as symmetry/ordering subtype OCD patients (Cavallini *et al.*, 2002). The S/L genotype of the 5-HTTLPR polymorphism was reported among the majority of OCD patients who were responders to a 12-week treatment period with 300mg venlafaxine (Denys *et al.*, 2007). However, eight studies reported no association at all between 5-HTTPR and OCD (Frisch *et al.*, 2000; Camarena *et al.*, 2001; Di Bella *et al.*, 2002b; Chabane *et al.*, 2004; Meira-Lima *et al.*, 2004; Wendland *et al.*, 2006; Dickel *et al.*, 2007; Saiz *et al.*, 2008).

Polymorphisms of the 5-HT<sub>1B</sub> receptor were studied by Mundo and colleagues in a large, Canadian family-based sample. They found a significant association between OCD and the G861 polymorphism of this gene. The G-allele was associated with OCD and predicted OC severity (Mundo *et al.*, 2002). Two subsequent studies also reported an association between OC severity and the G861 variant, although they did not find a significant association between G861 polymorphism and OCD (Camarena *et al.*, 2004; Levitan *et al.*, 2006). In an Italian family based study, no preferential transmission of either allele of the 5-HT<sub>1B/1D</sub> was observed (Di Bella *et al.*, 2002a).

The -1438G/A polymorphism of the 5-HT<sub>2A</sub> receptor gene has also been linked to OCD. Enoch and colleagues reported a higher frequency of the -1438G/A allele in female OCD patients compared to healthy women (Enoch *et al.*, 2001). A statistically significant difference in the frequency of the A-allele was also reported in a study with 55 children and adolescents with OCD compared to control subjects (Walitza *et al.*, 2002). Denys and colleagues found an association between the 5-HT<sub>2A</sub> G-allele in 156 OCD patients and a positive family history and an early onset of the disease compared to 134 control individuals (Denys *et al.*, 2006).

The G/G genotype of the 5-HT<sub>2A</sub> polymorphism was also reported amongst the majority of OCD patients who responded with a Y-BOCS decrease of more than 25 percent to a 12-week treatment period with 60mg paroxetine (Denys *et al.*, 2007). Difference in OCD phenotype may explain these discrepant findings. However, two studies found no association between 5-HT<sub>2A</sub> polymorphism and OCD (Dickel *et al.*, 2007; Saiz *et al.*, 2008).

A genetic study in several early-onset OCD probands found no evidence for functional mutations in the sequenced regions of 5-HTR<sub>2B</sub> (Kim *et al.*, 2000).

Cavallini and colleagues found no association between OCD and the CYS23Ser mutation of the 5-HT<sub>2C</sub> receptor

gene in a genetic study comparing 109 OCD patients with 107 healthy control subjects (Cavallini *et al.*, 1998).

The C178T variant of the 5-HT<sub>3A</sub> receptor influences, among others, 5-HT<sub>3</sub> receptor expression. In a family-based approach with 75 children and adolescents with OCD as well as their biological parents, no evidence for a preferential transmission of either allele of the 5-HT<sub>3A</sub> receptor was found. This is contrary to the involvement of the 5-HT<sub>3A</sub> receptor in OCD (Mossner *et al.*, 2007).

The results of genetic association studies are, as yet, inconsistent and, except for the 5-HT<sub>2A</sub> receptor, mainly negative.

### Animal models

In the past decades, OCD-like animal models have been developed using chemical, genetic and behavioral induction. Table 3 gives a summary of the different animal models for OCD available.

Suppression of spontaneous burying in the marble-burying behavior model was originally used as a measure of anxiolytic drug action. Analysis of the marble-burying behavior later led to the suggestion that it was more related to compulsive behavior (Joel, 2006).

The 5-HT<sub>1A</sub> agonists perospirone, MKC-242 and aripiprazole were tested in the marble-burying behavior model. All three inhibited marble-burying behavior. Inhibition of the behavior may be antagonized with WAY100135, a selective 5-HT<sub>1A</sub> antagonist (Abe *et al.*, 1998; Matsushita *et al.*, 2005; Egashira *et al.*, 2008). Ichumaru and colleagues demonstrated that the suppressive effect of fluvoxamine on marble-burying behavior may be inhibited by the 5-HT<sub>1A</sub> antagonist NAN-190 (Ichimaru *et al.*, 1995). Ketanserin, a 5-HT<sub>2A</sub> antagonist, had no effect on marble-burying behavior (Egashira *et al.*, 2008). However, YM992, a compound with selective 5-HT reuptake inhibition and 5-HT<sub>2A</sub> receptor antagonistic activity, significantly inhibited marble-burying behavior (Takeuchi *et al.*, 2002).

An extensive study examined the effects of 36 compounds, including typical, atypical and novel antipsychotics, on marble-burying behavior in mice. It concluded that the inhibition of marble-burying behavior may result from the interplay of several receptor systems, such as 5-HT<sub>2</sub> receptor blockade, 5-HT<sub>1A</sub> agonism and dopamine D<sub>2</sub> partial agonism (Bruins Slot *et al.*, 2008).

The adjunctive drinking in the scheduled-induced polydipsia (SIP) model decreased after acute administration of WAY-181187, a novel and selective 5-HT<sub>6</sub> receptor agonist, and several 5-HT<sub>2C</sub> receptor agonists (Bos *et al.*, 1997; Martin *et al.*, 1998; Dunlop *et al.*, 2006; Rosenzweig-Lipson *et al.*, 2007; Schechter *et al.*, 2007).

**Table 3** Summary of the animal models available for OCD

	Inductor	Face validity symptoms	Predictive validity	Reference
<b>Pharmacological models</b>				
Spontaneous alternation behavior	8-OHDPAT 5-HT <sub>1A</sub> agonist	Indecision (T-maze)	—	Seibell <i>et al.</i> , 2003
Spontaneous alternation behavior	8-OHDPAT 5-HT <sub>1A</sub> agonist	Perseveration (T-maze)	SSRI	Yadin <i>et al.</i> , 1991
Spontaneous alternation behavior	Quinpirole (D <sub>2</sub> agonist)	Perseveration (T-maze)	SSRI	Einat and Szechtman, 1995
Reinforced spatial alternation	m-CPP (5-HT <sub>1A</sub> /1B/2C agonist)	Persistence (T-maze)	SSRI	Tsaltas <i>et al.</i> , 2005
Singular behavior	DOI 5-HT <sub>2A</sub> /2C agonist	Head twitch	SSRI	Rojas-Corrales <i>et al.</i> , 2007
Singular behavior	m-CPP (5-HT <sub>1A</sub> /1B/2C agonist)	Self-grooming	5-HT depletion caused more grooming	Graf, 2006
Singular behavior	Oxytocin	Hyper-grooming	—	Marroni <i>et al.</i> , 2007
Motor behavior	Quinpirole (D <sub>2</sub> agonist)	Compulsive checking	SSRI	Szechtman <i>et al.</i> , 1998
<b>Behavioral models</b>				
Marble burying	—	Compulsive burying	SSRI	Njung'e and Handley, 1991
Scheduled induced polydipsia (SIP)	Food deprived/fixed time feeding	Excessive drinking	SSRI	Woods <i>et al.</i> , 1993
Signal attenuation	Food deprivation	Compulsive lever pressing	SSRI	Joel, 2006
Head dipping	—	Head dipping	—	Chou-Green <i>et al.</i> , 2003
Plastic-mesh screen chewing	—	Plastic-mesh screen chewing	—	Chou-Green <i>et al.</i> , 2003
<b>Genetic models</b>				
Sapap3-mutant mice		Compulsive grooming behaviour	SSRI	Welch <i>et al.</i> , 2007
5-HT <sub>7</sub> receptor knockout mice		None	—	Hedlund and Sutcliffe 2007
5-HT <sub>2C</sub> receptor knockout mice		Compulsive like behaviour: chewing of non-nutritive clay, chewing patterns on plastic-mesh screens, head dipping	—	Chou-Green <i>et al.</i> , 2003
Hoxb8 mutant mice		Excessive grooming	—	Greer and Capecchi, 2002
DAT KD mice		Rigid syntactic grooming chain patterns	—	Berridge <i>et al.</i> , 2005
DICT-7 mice		Compulsive behavior	—	Campbell <i>et al.</i> , 1999

In the signal attenuation rat model, the 5-HT<sub>2A</sub> antagonist MDL as well as the 5-HT<sub>2A/2C</sub> agonist DOI had no effect on compulsive lever pressing (Flaisher-Grinberg *et al.*, 2008). However, the 5-HT<sub>2C</sub> antagonist RS 102221 decreased compulsive lever pressing after systemic administration, and after administration directly into the orbitofrontal cortex (Flaisher-Grinberg *et al.*, 2008).

Naratriptan, a selective 5-HT<sub>1D</sub> receptor agonist, did not exacerbate compulsive behavior in the reinforced spatial alternation animal model. The fact that mCPP, a non-selective 5-HT receptor agonist acting at the 5-HT<sub>2C</sub>, 5-HT<sub>1B/1D</sub> and 5-HT<sub>1A</sub> receptors, did increase

compulsive behavior in this animal model speaks against the involvement of the 5-HT<sub>1B/1D</sub> receptor in the OCD pathophysiology (Tsaltas *et al.*, 2005).

The mCPP-induced self-grooming in rats was reversed by a subtype-selective 5-HT<sub>2C</sub> antagonist SB-242084, but not by the subtype-selective 5-HT<sub>2B</sub> receptor antagonist SB-215505 (Graf *et al.*, 2003).

Several animal models for OCD originated from genetic modification of the serotonergic system. The 5-HT<sub>2C</sub> receptor knockout mouse exhibited compulsive behavior. It chewed more clay, produced a distinct pattern of 'neat' chewing of plastic screens, and exhibited reduced

habituation of head-dipping activity. This suggests that the 5-HT<sub>2C</sub> receptor knockout mouse could be a promising model of compulsive behavior (Chou-Green *et al.*, 2003). Hedlund and colleagues investigated mice lacking the 5-HT<sub>7</sub> receptor compared to wild-type mice in three behavioral models for OCD. The 5-HT<sub>7</sub><sup>-/-</sup> mice buried fewer marbles than 5-HT<sub>7</sub><sup>+/+</sup> mice in the marble-burying behavioral model. Furthermore when the 5-HT<sub>7</sub><sup>+/+</sup> mice were treated with SB-269970, a selective 5-HT<sub>7</sub> receptor antagonist, they also buried fewer marbles than the 5-HT<sub>7</sub><sup>+/+</sup> mice treated with vehicle. In other words, inactivation as well as blockade of the 5-HT<sub>7</sub> receptor had a positive effect on OCD activity. However, in the two other behavioral models, head dipping and plastic-mesh screen chewing, no difference was found between the 5-HT<sub>7</sub><sup>-/-</sup> mice and wild-type mice (Hedlund and Sutcliffe, 2007).

Preclinical research into 5-HTT function has progressed rapidly since 5-HTT knockout animal models became available. However, as yet, research on the 5-HTT knockout rat or mouse behavior paradigms has not directly linked any behavioral deviations to OCD (Mathews *et al.*, 2004; Homberg *et al.*, 2007; Olivier *et al.*, 2008).

In summary, preclinical research gives conflicting results. It suggests involvement of the 5-HT<sub>2C</sub> receptor and provides interesting preliminary results in animal models for the 5-HT<sub>6</sub> and 5-HT<sub>7</sub> receptors.

## Conclusion

There is compelling evidence that the serotonergic system plays a major role in the treatment of OCD. Pharmacotherapeutic studies have shown that SSRIs are more effective in achieving clinical response compared to placebo, and that atypical antipsychotics, which have a high affinity for 5-HT<sub>2A</sub> and 5-HT<sub>2C</sub> receptors may augment the effect of SSRIs. However, these findings do not necessarily reflect the existence of a neurobiological abnormality in the central serotonergic system in OCD. SSRIs may modulate serotonin via an intact serotonergic system to compensate for the underlying pathogenesis that is related to another neurotransmitter system.

A general survey of the specific role of 5-HT transporters and 5-HT receptors in OCD arrives at inconsistent conclusions. Though an impaired 5-HTT function is suggested by some neuroimaging studies, others indicate that successful SSRI treatment is associated with normalization of the dopamine function. Genetic and animal studies have provided insufficient evidence to implicate a fundamental role for 5-HTT in the pathophysiology of OCD. As yet the role of 5-HT<sub>1A</sub> receptors in OCD is unclear, since 5-HT<sub>1A</sub> agonists as well as 5-HT<sub>1A</sub> antagonists improve OC symptoms in pharmacologic challenge

studies. Assuming that chronic SSRI treatment leads to a desensitization of the terminal 5HT<sub>1B/1D</sub> receptor, some authors have hypothesized that 5HT<sub>1B/1D</sub> receptors are supersensitive in OCD, resulting in chronic reductions in synaptic levels of 5-HT (Moret and Briley, 2000). There is circumstantial evidence that the 5-HT<sub>2A</sub> receptor may be of particular relevance to OCD. Genetic studies linked the -1438G/A polymorphism of the 5-HT<sub>2A</sub> receptor gene to OCD, but non-selective 5-HT<sub>2A</sub> agonists as well as antagonists have a positive effect on OC symptoms. Reports on involvement of the 5-HT<sub>2A</sub> receptor in neuroimaging and animal research are inconsistent. Though pharmacological challenges with mCPP suggest a role for the 5-HT<sub>2C</sub> receptor, animal models report conflicting results, since 5-HT<sub>2C</sub> agonists as well as antagonists reduce or induce obsessive-compulsive behavior. At this moment, there is no evidence to underscore a role for the 5-HT<sub>2B</sub>, 5-HT<sub>3</sub>, 5-HT<sub>6</sub>, or 5-HT<sub>7</sub> receptors in OCD.

In summary, direct evidence for an abnormality in the serotonergic system in the pathophysiology of OCD is still scarce. Hence, it is open to discussion whether the serotonergic system plays a primary role in the pathophysiology OCD or is secondarily involved due to the efficacy of SSRIs. Reasonably, SSRIs modulate an intact serotonergic system to compensate for another neurotransmitter mechanism. Several observations lend support to the assumption that inhibition of 5-HTT is not causally related to the genesis of the disorder (Baumgarten and Grozdanovic, 1998).

First, the mean response rate in OCD is 50 percent or less (Denys *et al.*, 2002), indicating that for a substantial number of patients 5-HTT inhibition is insufficient to alleviate OC symptoms. Phenotypic heterogeneity may partly explain this phenomenon, as, for example, patients with contamination fear respond more favorably to SSRIs than do patients from the subtype symmetry/perfectionism/hoarding (Denys *et al.*, 2004a). Second, the doses of antidepressants necessary for OCD are substantially higher than those for depression or anxiety disorders, and also substantially higher than necessary to completely block the 5-HTT (Kent *et al.*, 2002). Third, the synthesis of 5-HT depends on the availability of tryptophan in the brain. Depletion studies in depression have shown deterioration in patients on antidepressants in remission (Neumeister, 2003), but no worsening of symptoms was seen in patients with OCD who underwent a tryptophan-depletion paradigm (Berney *et al.*, 2006). Fourth, the therapeutic effects in OCD are usually not seen within 8 weeks of treatment, which is much later than in patients with depression. El Mansari and colleagues have argued, on the basis of their electrophysiological work, that this difference in onset of action between depression and OCD can be accounted for by a greater delay in effect of SSRIs on 5-HT release in

the orbitofrontal cortex (OFC), a brain region supposedly implicated in OCD, as compared to other brain regions (El Mansari and Blier, 2006). According to these investigators, this delay in effect in the OFC might be explained by a slower desensitization of the 5-HT<sub>1B</sub> autoreceptors in this region. They also used this finding as an argument to explain why, in OCD, larger doses of SSRIs are needed. In line with this finding, Dannon and colleagues have reported pindolol, a non-selective 5-HT<sub>1A</sub> receptor antagonist, to hasten the effect of SSRIs in OCD patients (Dannon *et al.*, 2000). They also suggest that the effect of SSRIs in OCD might be explained by the delayed stimulation of the postsynaptic 5-HT<sub>2A</sub> receptors in the OFC. If this were to be true, one would expect mirtazapine (which among others is a 5-HT<sub>2A</sub> receptor antagonist) and atypical antipsychotics that also have antagonistic effects at this receptor to attenuate the effect of SSRIs. Clinical studies with these drugs, however, have shown the opposite. Mirtazapine, although not effective by itself, has been shown to hasten the effect of paroxetine (Pallanti *et al.*, 2004), and several studies have shown that atypical antipsychotics augment the effects of SSRIs in refractory OCD patients (Bloch *et al.*, 2006). Moreover, mCPP, a non-selective 5-HT<sub>2</sub> receptor agonist, is either not effective or causes a worsening of OC symptoms after acute administration (Charney *et al.*, 1988; Goodman *et al.*, 1995; Hollander *et al.*, 1992; Ho Pian *et al.*, 1998; Gross-Isseroff *et al.*, 2004).

In conclusion, future research should focus much more on the interaction of the serotonergic system with other neurochemical systems, such as dopamine and glutamate. There is some evidence that dopamine might be involved in OCD. Atypical antipsychotics with potent 5-HT<sub>2A</sub>, 5-HT<sub>2C</sub> and D<sub>2</sub> antagonistic properties have anti-obsessional properties as additional therapy to SSRIs. Denys and colleagues found that the combination of quetiapine and fluvoxamine may cause a synergistic dopamine increase in the prefrontal cortex and thalamus (Denys *et al.*, 2004b). Moreover, SPECT and PET studies hint at decreased D<sub>2</sub> receptor binding in the ventral striatum (Denys *et al.*, 2004c), and indicate that successful SSRI treatment in OCD is associated with normalization of the dopamine function. Additionally, more selective agents need to be developed to investigate the specific role of the different receptors of the 5-HT system. In the pipeline are a series of 5-HT<sub>2C</sub> agonists which are being investigated by Hoffman-La Roche, while Janssen Pharmaceutica is studying an azeprine derivative with mixed 5-HT<sub>2A/2C</sub> antagonism for use in OCD. Furthermore, a 5-HT<sub>1B/1D</sub> antagonist is being investigated by GlaxoSmithKline, and Vanderbilt University is looking at a selective 5-HT<sub>3</sub> antagonist (Davidson and Bjorgvinsson, 2003). The development of better animal models will be a tool to further

enrich our understanding of OCD. OCD is a complex psychiatric disorder affecting cognition, affect and volition. It is therefore unlikely that one single neurotransmitter is involved in its pathophysiology.

# The Role of Serotonin in Attention-Deficit Hyperactivity Disorder (ADHD)

Robert D. Oades\*

*Clinic for Child and Adolescent Psychiatry and Psychotherapy, University of Duisburg-Essen, Essen, Germany*

**Abstract:** The symptoms of childhood attention-deficit hyperactivity disorder (ADHD) cover the domains of cognition, impulsivity and motor control, and often embody motivational/emotional features. Prevalence of the combined-type disorder may decrease with age, but the former features predominate increasingly through adolescence to adulthood. The widespread innervation through the CNS by fibers containing serotonin (5-HT) means that, as cause or effect, it is likely that 5-HT is involved where function in these domains is impaired. The relative success of treatment with catecholaminergic agents has overshadowed investigation of the reasons for the partial response of half of these patients. This chapter suggests that anomalous 5-HT function may provide one potential explanation. The best evidence lies with the high heritability of the disorder, where several genes with small effect contribute to the availability of 5-HT and its metabolism. Extra-neuronal availability is under the control of enzymes responsible for 5-HT synthesis, and its removal depends on breakdown or reuptake. Alleles are expressed in cases with ADHD that disturb this availability; they can be over- or under-expressed, depending on phenotype (e.g., impulsivity). The effect of altered levels of 5-HT is mediated by the expression of pre- and postsynaptic receptors of the 5-HT<sub>1</sub> and 5-HT<sub>2</sub> families. Neuropsychological and neurophysiological studies show that the processes affected range from perception, through attention to motivationally guided learning and mood. While the function of a range of brain regions may be involved, the thalamus and frontal lobes are taken as potentially influential examples. Study in this field is in its infancy, and many putative interactions (e.g., between genes, gene/environment, co-morbid problems, development and motor function) require closer investigation.

**Keywords:** ADHD, attention, co-morbidity, genetics, impulsivity, monoamine oxidase, serotonin, transporter, tryptophan hydroxylase.

**Abbreviations:** ADHD, attention-deficit hyperactivity disorder: ct – combined type, ia – inattentive type, hi – hyperactive-impulsive type; *DSM*, *Diagnostic and Statistical Manual of the American Psychiatric Association*; EEG, electroencephalogram; ERN, event-related negativity; ERP, event-related potential; (f)-MRI, (functional)-magnetic resonance imaging; 5-HIAA, 5-hydroxyindole-acetic acid; 5-HT, serotonin/5-hydroxy-tryptamine; 5-HT<sub>1/2</sub> A/B, serotonin receptor subtypes; HTR1/2 A/B, genes for serotonin receptor subtypes; 5-HTTLPR, 5-HT transporter linked promoter region; MAOA/B, monoamine oxidase (type A, type B); PET, positron emission tomography; SNP, single nucleotide polymorphism; TPH, tryptophan hydroxylase (genes TPH1, TPH2); VNTR, variable number of tandem repeats.

## Introduction

ADHD is a developmental disorder with a childhood onset, where symptoms usually set in before the age of 6 years. The diagnosis with a functional impairment is made worldwide in about 2–7 percent of youngsters (Faraone *et al.*, 2003). Rates at the lower end of this range are often reported outside the USA using the criteria of the World

Health Organization (ICD-10) for the similar hyperactivity disorder. Higher rates have often been reported from the USA, where the research diagnostic criteria of the American Psychiatric Association (*DSM-IV*) constitute the preferred diagnostic instrument. To a large extent, the variability may reflect the assessment of a clinically significant functional impairment. For those with the childhood disorder, this persists in about two from three cases into adolescence. In about one in three cases the childhood condition continues on into adulthood, where it is often overshadowed by co-morbid problems (Cumyn *et al.*,

\*E-mail: robert.oades@uni-due.de

2007). ADHD presents more often in male than female children (*ca.* 3–5:1; Buitelaar *et al.*, 2006), but the ratio tends to even out among adults (Biederman *et al.*, 2004).

As the name denotes, problems in ADHD of the combined type (ADHDc) cover cognitive (attention-related) and motor (restlessness) functions, and impulsivity in both of these domains. Smaller numbers of patients can present with problems in only one of these domains ('inattentive', ADHDi; and 'hyperactive-impulsive', ADHDh). The characteristic of impulsivity may be extended to cognitive function (e.g., rapid and risky decisions; White *et al.*, 1994; Oades, 2008), but also to motivation, where the term typically reflects a preference for immediate reward. This feature may also reflect a further specific subtype or endophenotype within the mantle diagnosis of ADHD (Sonuga-Barke, 2005). Arguably also falling within the motivational domain may be problems concerning the control of affect that can have internalizing features (e.g., lack of self-esteem, anxiety) or an externalizing nature (e.g., aggressive outbursts). Both can lead to poor social networking, and both can occur in one and the same patient (Boylan *et al.*, 2008). However, it should also be emphasized, as noted in the *DSM*, that these features are 'often' present; they are not necessarily evident all the time. Many current studies of ADHD are focusing on the frequent finding of an increased moment-to-moment variability of the laboratory measure under study. Taking into consideration the range of cognitive and motor functions, discussed elsewhere in this volume, in which serotonin (5-HT) plays an important role, then one can reasonably suspect 5-HT activity to be altered in ADHD: be this as an effect of changes in the function of other neural systems or itself a cause of the anomalous manifestation of cognitive, motivational and motor function (Oades, 2007, 2008).

A significant confound for the interpretation of many studies of patients with ADHD involves the role of co-morbid problems. This is particularly marked in adult cases, where more than 80 percent may exhibit co-morbid psychiatric problems and over half express symptoms satisfying two or more co-morbid disorders (Cumyn *et al.*, 2007). In children and adolescents, more than one in five may have a co-morbid anxiety, mood or depressive disorder, and a similar proportion are reported to have a conduct or oppositional defiant disorder (*DSM-III-R*; August *et al.*, 1996). It is widely acknowledged that children with ADHD can show autistic symptoms that may reflect a genetic overlap between the two disorders (Ronald *et al.*, 2008). A recent study showed that as many as one in four autistic children showed enough clinical features to be diagnosed with ADHD (Goldstein and Schwebach, 2004). Lastly, around 20 percent of children with ADHD may also show co-morbid tic disorders (Banaschewski *et al.*, 2007). The relevance of this is that each of these

adjunctive problems has been associated with dysfunctional 5-HT systems – for example, mood, depression and internalizing problems (Stahl, 1997; Schmidt *et al.*, 2007), conduct and antisocial disorders (Stadler *et al.*, 2004; van Goozen *et al.*, 2007), autistic spectrum (Whitaker-Azmitia, 2005; Murphy *et al.*, 2006) and tic or Tourette syndrome (Haugbol *et al.*, 2007; Wong *et al.*, 2008).

With these issues in mind, this chapter discusses first the more direct categories of evidence for a contribution of 5-HT to the ADHD phenotype from genetics studies, followed by the often less direct evidence of the role of 5-HT activity in the impairments in the dimensions of impulsivity and cognition-related processes. The undoubted contributions of anomalous noradrenergic and dopaminergic function to the full expression of ADHD are not the focus of this chapter.

## Genetics

In psychiatry, as in other fields of medicine, there is a current explosion of genetics studies purporting to find an association between a marker for an unusual physiological function in the brain (e.g., a single nucleotide polymorphism, SNP) and the feature encoded (e.g., a form of transmitter receptor or growth modulator). However, determining the criteria for a reliable result is a process still at an early stage of development, where most mental disorders are polygenic, with many alterations of small effect. Examples of methods that are still developing include the determination of an adequate sample size (the need for hundreds or, better, thousands of cases for statistical power), the nature of data cleaning and the conservatism appropriate to the performance of hundreds of statistical tests. Nonetheless, with these caveats in mind, the importance of 5-HT synthesis, breakdown, transport and receptor type for ADHD phenotypes will now be considered.

### 5-HT synthesis

The rate-limiting enzyme for the synthesis of 5-HT is tryptophan hydroxylase. In brain tissue, it is encoded by TPH2 on chromosome 12Q21.1. Less likely to be relevant to ADHD is TPH1, which encodes the enzyme more usually found peripherally (Walther *et al.*, 2003). Eight SNPs that influence TPH2 activity and the supply of 5-HT have been examined. Initially, an Irish study of 179 families reported an association with ADHD for three alleles that was enhanced by paternal transmission (Sheehan *et al.*, 2005). Although this group could not replicate their results in a UK sample (Sheehan *et al.*, 2007),

the IMAGE study, based on 12 European centers (674 families, 776 children), partially confirmed the influence of at least one of these SNPs (Brookes *et al.*, 2006), albeit the significance of a genome-wide association did not survive correction (Lasky-Su *et al.*, 2008a). Nevertheless, nominally significant associations have been reported in the IMAGE sample, specifically with impulsive symptoms (Oades *et al.*, 2008). Three SNPs were over-expressed in association with cognitive impulsivity; a further SNP was under-expressed in association with impulsive aggressive symptoms. There is modest evidence suggestive of a paternal influence on TPH2 transmission (Anney *et al.*, 2008a). A report based on 103 German families (225 children) also found a trend for preferential transmission of two SNPs in the regulatory region for TPH2 (Walitza *et al.*, 2005). One of these markers is of particular interest, as it lies in the promoter region for TPH2 and leads to a reduction of TPH2 transcriptional activity (Scheuch *et al.*, 2007).

From a functional point of view, TPH alleles can moderate working memory performance (Reuter *et al.*, 2008) and the topography of potentials elicited by stimuli requiring response inhibition (Baehne *et al.*, 2008). Both features are typically altered in patients with ADHD (Nigg *et al.*, 2005). An examination of 8 SNPs, overlapping with those studied above (Manor *et al.*, 2008), showed borderline associations in an Israeli sample of 344 patients. The associations with the subjects' accuracy (errors of omission not commission) and reaction times, and their variability while performing a sustained attention task, were striking. These are behavioral measures that characterize impaired ADHD performance in most studies (Willcutt *et al.*, 2005). Initially surprising was that the improved performance after methylphenidate treatment was also related to TPH2, as methylphenidate has no direct influence on 5-HT function (Leonard *et al.*, 2004). However, this result would be compatible with the impaired regulatory activity for the enzyme described above, and a reduced inhibitory control of 5-HT in its well-known interactions with DA (Oades, 2008).

Lastly, it may be instructive to point to potential gene-environmental interactions that are gaining increased attention. Work with rodent stress models has shown that increasing glucocorticoid levels can reduce the expression of TPH2 and 5-HT synthesis (Clark *et al.*, 2008). In the IMAGE study, TPH genes were among a number of monoaminergic candidate genes that were associated with measures of the maternal expressions of criticism toward their offspring and the conduct problems arising (Sonuga-Barke *et al.*, 2008). Indeed, a subgroup of this patient sample was exposed to experimenter-determined degrees of parental warmth or negative hostile remarks. In contrast to those receiving encouraging remarks,

patients with increased levels of perceived criticism failed to show the normal circadian decrease of salivary cortisol levels: warmth was associated with the protective effect (Christiansen *et al.*, 2010). Adverse social environments (e.g., maternal hostility) may 'switch off' or socially benign environments 'switch on' genetic effects, whereby 5-HT availability plays a role. Separate phenotypes may be associated with increases and decreases of levels of 5-HT made available through the activity of the enzyme responsible for its synthesis.

### 5-HT breakdown

The availability of 5-HT in and around the synapse depends on the rate of synthesis and release, reuptake and catabolism. The enzyme responsible for the catabolic breakdown (oxidative deamination) of dopamine, noradrenaline and 5-HT is for the most part monoamine oxidase A (MAOA: chromosome locus Xp11.23). Thus, it should be borne in mind that any findings relating to MAOA may influence monoamines other than 5-HT. However, studies of knockout mice lacking MAOA confirm larger alterations in the 5-HT than catecholamine systems (Cases *et al.*, 1995; Evrard *et al.*, 2002). In detail, 5-HT levels were decreased in the hippocampus, frontal cortex and dorsal raphe, the transporter was down-regulated, and in the dorsal raphe (the source of many 5-HT projections) the 5-HT<sub>1A</sub> autoreceptors were desensitized and reduced in number. Consistent with this, an over-expression of MAOA (at least in healthy women) has been associated with greater 5-HT<sub>1A</sub> availability (Mickey *et al.*, 2008). Perhaps regard for gender is crucial. A study of girls and boys with ADHD reported that one particular haplotype (ATT) was associated with working memory performance in the former but motor control in the latter (Rommelse *et al.*, 2008). This could reflect influences on separate transmitter systems.

Among a number of polymorphisms examined in studies of ADHD are those with a variable number of tandem repeats (VNTR) in the promoter region of the MAOA gene, in which there may be shorter or longer repeat sequences that give rise to forms with lower or higher enzymatic activity, respectively. Modest associations for several *long* alleles giving rise to high-activity forms of MAOA have been reported to be preferentially transmitted in ADHD (Jiang *et al.*, 2001; Payton *et al.*, 2001; Manor *et al.*, 2002; Domschke *et al.*, 2005) in samples of 82, 110 and 179 cases, respectively. However, Domschke and colleagues were unable to replicate the results for the alleles studied in the other laboratories. They went on to suggest it is one (or more) of the *shorter* alleles that may be preferentially transmitted. This is supported by other

reports with Caucasian and Asian samples (Brookes *et al.*, 2006; Das *et al.*, 2006). Yet while Brookes and colleagues found gene-wide significance for a marker in this region, Ribases *et al.* (2007) could not confirm this. Rather, they emphasized a marker in the overlapping gene for MAOB. Indeed, one small study (Lung *et al.*, 2006) could find no evidence at all for long or short alleles being associated with ADHD.

Contributing to these disparate results may be the uncontrolled co-morbid problems of the cases examined. In a normal population, low-activity alleles were associated with impulsivity and aggressive tendencies (Manuck *et al.*, 2000). Indeed, trends for association of the low-activity allele with ADHD boys showing disruptive behavior have been reported (Lawson *et al.*, 2003; Malmberg *et al.*, 2008). It appears that the associations of MAOA markers have less to do with the diagnosis of ADHD than with antisocial behavior seen in the context of ADHD (Thapar *et al.*, 2007).

An alternative explanation should be considered; namely, that both high- and low-activity markers may be relevant. For example, an fMRI study of subjects under dietary control for tryptophan, a 5-HT precursor, showed that decisions about smaller and larger rewards after shorter and longer delays were under the differential control of 5-HT levels (Tanaka *et al.*, 2008). Reward prediction at short timescales (under low levels of 5-HT) was associated with activity in the ventral striatum, but prediction at long timescales was correlated (under high levels of 5-HT) with activity in the dorsal striatum (Schweighofer *et al.*, 2008). The results represent essentially a gradient where low and high levels both contribute to components of the decision and the potential to be impulsive. However, care must be taken in the interpretation of these results. Manor *et al.* (2002) found that an association in children with ADHD between the long MAOA allele and impulsive errors of commission on a test of sustained attention was strongly attenuated following methylphenidate treatment. As this medication inhibits catecholamine reuptake, the apparent association with impulsive decisions may not reflect 5-HT activity.

The interest in MAO here lies with demonstrations of the influence that an interference with 5-HT breakdown can have in development and neurotransmission: this could be crucial for understanding the origins of developmental disorders such as ADHD. In animal models, treatment of pregnant rats with MAO inhibitors severely affected 5-HT (not dopamine) neurotransmission and led to hyperactivity and impulsivity in the offspring (Whitaker-Azmitia *et al.*, 1994). In the case of mice, interference with MAO early in development rather than in the adult leads to enhanced aggressive responses later in the maturation process (Mejia *et al.*, 2002). Genetically speaking, it is the low-expression variant that is associated

with aggression in humans (Meyer-Lindenberg *et al.*, 2006). There is strong evidence for an association of MAOA expression leading to externalizing disorders such as ADHD and conduct disorder (Baler *et al.*, 2008). This may reflect on an allele that itself induces high activity, or, as Baler and colleagues emphasize, a genetic interaction with environmental risk. Baler *et al.* (2008) show that a genotype that leads to reduced fetal MAOA activity can modulate development and induce changes of morphology in limbic and cognitive areas of the brain (reductions in the amygdala and cingulate gyrus, increases in the lateral orbito-frontal cortex; Meyer-Lindenberg *et al.*, 2006). Alone, the behavioral outcome may remain within the normal range, but neural differentiation will also be influenced by prenatal exposure to gonadal steroid hormones. The extent to which this experience facilitates aggressive or impulsive tendencies also depends on exposure to stress: the threshold for expressing disruptive behavior may be lower if the foregoing conditions of genotype and brain circuitry are met. Some claim that the risk of developing conduct disorder is even greater if the fetus is exposed to the environmental feature of a mother who smokes tobacco (components of tobacco smoke can lower fetal MAO activity and influence several neurodevelopmental processes, including the control of emotions). The message is that environmental constellations may regulate the outcome, whether the expression of the genotype alone facilitates more or less activity.

Thus, in the present case, the low-activity form of MAO may be involved only where the children are at risk and, for example, may have already been maltreated (Caspi *et al.*, 2002). Although ADHD is often grouped among the externalizing disorders, the evidence of association with MAOA influence on 5-HT activity is strongest where conduct disorder is diagnosed at least as a primary disorder (Kruesi *et al.*, 1992; van Goozen and Fairchild, 2006), but perhaps also as a co-morbid trait. In many cases, ADHD with conduct problems should be considered a separate diagnostic entity (Christiansen *et al.*, 2008).

Clearly, gene-environment associations merit closer attention. It may also be appropriate not to neglect MAOB, which has a considerable structural and genetic overlap with MAOA, and is an indicator of 5-HT as well as dopamine activity (Oreland and Hallman, 1995). MAOB polymorphisms have been nominally implicated in contributing to ADHD (Ribases *et al.*, 2007; Li *et al.*, 2008). A recent twin study (Malmberg *et al.*, 2008) showed that low MAOB activity could relate to impulsive tendencies and monotony avoidance. As with 5-HT in the previous section, genetic variants reflecting high and low rates of breakdown may be associated with different phenotypes, and their effect may be gender sensitive. Possibly, shorter sequences in the promoter region are associated with delayed discounting, hyperactivity

and conduct problems (e.g., ADHDct and ADHDhi), and cognitive difficulties arise in the presence of the longer variant (e.g., ADHDia), with expression depending on developmental experience.

### 5-HT transport and uptake

The uptake efficiency of the 5-HT transporter (5-HTT), with a genetic locus on chromosome 17q11.1–12, has a major influence on the perisynaptic availability of 5-HT and the likelihood of postsynaptic neuromodulation by 5-HT. Most studies relating to ADHD concern variants of three polymorphisms of this locus (SLC6A4): (1) an in/del promoter polymorphism (5-HTTLPR); (2) a VNTR polymorphism in intron 2 (STin2); and (3) an SNP in the 3'-untranslated region (3'UTR). The 5-HTTLPR has short (14) and long (16) repeat sequences, but the STin2 polymorphism also has shorter and longer repeat sequences (9, 10, 11, and 12). Homozygotes with the 5-HTTLPR long allele (in contrast to homo- or heterozygotes for the short form) are associated with increased 5-HT uptake, transporter expression, and efficiency of transcription (Lesch *et al.*, 1996; Bradley *et al.*, 2005).

Initially, based on several relatively small samples, it seemed that ADHD cases were characterized by either a significantly low frequency of the short allele, or a high frequency of the long (l/l) allele in the 5-HTTLPR (Manor *et al.*, 2001; Seeger *et al.*, 2001; Kent *et al.*, 2002; Retz *et al.*, 2002; Zoroglu *et al.*, 2002). By 2005, a pooled odds ratio of 1.31 had been calculated (95% CI 1.09–1.59) for the long allele (Faraone *et al.*, 2005). This result was supported by studies of 250 children showing the most ADHD features in a normal population of 3819 children (Curran *et al.*, 2005) and an association with ADHD features in 184 delinquents (Retz *et al.*, 2008).

However, this was then followed by a sequence of studies yielding negative results in children and adults, from Caucasian as well as Asian samples (Langley *et al.*, 2003; Xu *et al.*, 2005; Banerjee *et al.*, 2006; Wigg *et al.*, 2006; Grevet *et al.*, 2007; Guimaraes *et al.*, 2007; Heiser *et al.*, 2007). Most recently, no association for 5-HTTLPR or STin2-VNTR was found in the IMAGE sample of 1166 ADHDct cases or in a sub-sample of 199 cases with comorbid mood disorder (Xu *et al.*, 2008). However, demonstrating the potential merit of looking for intermediate phenotypes, separate analyses using a family-based association test on repeat polymorphisms (microsatellites) of the STin2-VNTR provided a modestly significant association with symptoms associated with cognitive (not aggressive) impulsiveness for the 12 vs 9 and 10 repeat alleles and not for the short or long repeats of the promoter region for the 5-HTTLPR (Oades *et al.*, 2008).

Fewer groups have studied the STin2 polymorphism, and in general their results lead to equivocal conclusions.

Initially, Zoroglu *et al.* (2002) claimed that the absence of the 12 repeat variant characterized their ADHD sample. However, in India a small group of subjects showed a maternally biased transmission (Banerjee *et al.*, 2006), and borderline support for an association with attentional features was described for a Korean sample (Kim *et al.*, 2005). Currently, negative findings predominate (Langley *et al.*, 2003; Curran *et al.*, 2005; Xu *et al.*, 2005, 2008; Heiser *et al.*, 2007). Despite an early description of preferential transmission for the T allele of the 3'UTR (Kent *et al.*, 2002), this has not been confirmed (Curran *et al.*, 2005; Xu *et al.*, 2005; Wigg *et al.*, 2006; Heiser *et al.*, 2007).

It is unfortunate that both a series of 'false positive' reports as well as failed replications have failed to look for associations with other genes or gene–environment interactions. In contrast to the above reports on the long allele of the 5-HTTLPR, but consistent with an early report that ADHD cases may have fewer uptake binding sites (Stoff *et al.*, 1987), some trends for a preferential transmission of the short allele for the 5-HTTLPR have been described (Heiser *et al.*, 2007; Li *et al.*, 2007; Nyman *et al.*, 2007). Indeed, Schmidt and colleagues (2007), in a study of 107 normal 7-year-olds, found that if the short form is expressed along with a long allele from the DRD4 gene, then there is a marked association with increased internalizing and externalizing symptoms. The presence of the long allele of the promoter seemed to be protective. The association of the over-expression of 5-HT markers with cognitive impulsivity has been mentioned above: under-expressed, in this study, were SNPs for the dopamine transporter and D1 receptor (Oades *et al.*, 2008). Such results argue for more intensive study of subtypes of patient defined by endophenotype, and with particular regard for 5-HT/dopamine interactions.

A further example from outside the field of ADHD studies lies with the dramatic relationship between the volume of parts of the thalamus, the 5-HTT short genotype and various mood disorders (Young *et al.*, 2008). This may be pertinent and illustrative, as similarly dramatic and much neglected is the extensive concentration of dopamine uptake sites in the human thalamus (Garcia-Cabezas *et al.*, 2008), especially in nuclei where some of the highest levels of 5-HT innervation and of 5-HTT in the brain are to be found (Lavoie and Parent, 1991; Frankle *et al.*, 2004; Figure 1). Of particular interest are some of the 'aspecific' nuclei, such as the reticular and lateral habenula nuclei. These have recently been shown, from neurophysiological studies of non-human primates, to exert prominent roles in selective attention to ascending sensory information in the geniculate (McAlonan *et al.*, 2008), and in responses to the valence of these stimuli and reinforcement prediction (Hong and Hikosaka, 2008), respectively. Levels of 5-HT (reuptake inhibition, as well as mRNA expression of

**Figure 1** (Left) Darkfield photomicrographs depicting 5-HT innervation in different thalamic nuclei of the squirrel monkey. (A) Relatively weak innervation of the habenula. Martinez-Sanchez and C. Cavada, Universidad Autónoma de Madrid, Spain.

5-HT<sub>1B</sub> sites, and 5-HT<sub>7</sub> receptors) are also notably high in posterior regions such as the intralaminar as well as the mediodorsal nuclei (Alelu-Paz and Gimenez-Amaya, 2008). The latter part of the thalamus is well known for projecting to the same frontal regions innervated by the mesocortical dopamine system, in which anomalous activity can contribute to ADHD. In turn, these thalamic regions are intimately involved in functions ranging from cortical activation to maintaining the frontal involvement in working memory (Monckton and McCormick, 2002). Against a background of major dopamine/5-HT interactions in the brain (Oades, 2008), polymorphisms with small effect in these two systems may together in the thalamus (among other regions) have considerable repercussions for cerebral function relevant to ADHD.

Consideration of the importance of interactions between genes has already given rise to some investigation of the potential for subgroups of ADHD patients. Cadoret *et al.* (2003) observed, in a group of adoptees at high risk for externalizing disorders, that the males developing these conduct problems more often carried the short allele than

the females in the group. Indeed, in a population of twins assessed for ADHD ( $n = 247$ ), the heterozygote was predictive for conduct disorder in the boys (Malmberg *et al.*, 2008). In their study of delinquents, Retz and colleagues (2008) show that in the presence of a history of childhood adversity, the presence of the short allele is associated with the presence of ADHD features. In turn, there is also evidence that childhood aggression is related to the expression of the low-activity variant (Beitchman *et al.*, 2006, 2008; Haberstick *et al.*, 2006).

To sum up, it seems more than likely that changes, up and down, in the level and function of 5-HT around the synapse, as controlled by the uptake site, are related to subgroups of ADHD patients. These forms may be defined by co-morbidity, or endophenotype defined by temperament (e.g., opposition; Malmberg *et al.*, 2008) or neuropsychological control (e.g., cognitive impulsivity; Oades *et al.*, 2008). As in previous sections, interactions with gender and environment must be taken into consideration, but while the high-activity long form of the promoter may be associated with inappropriate cognitive

processes, the shorter form may permit poor control of externalizing tendencies.

Either way, it should not be overlooked that persistent high or low levels of 5-HT, controlled by reuptake efficacy, will have effects on the numbers of pre- and postsynaptic 5-HT receptors. Thus, for example, knockout mice without the transporter show reduced 5-HT<sub>1A</sub> binding in the brainstem, but increases in forebrain regions (Fabre *et al.*, 2000). This provides substance for the next section on 5-HT receptors.

### *Pre- and postsynaptic 5-HT receptors*

To date, most work has been directed towards the 5-HT<sub>1</sub> and 5-HT<sub>2</sub> families of receptors, rather than the 5-HT<sub>3–7</sub>-related binding sites. Thus, a concentration here on studies of the former should not preclude a serious consideration of potential contributions of the latter to ADHD in the future. Relevant studies have mostly concerned the 5-HT<sub>1A</sub>, <sub>1B</sub>, <sub>1E</sub> and 5-HT<sub>2A</sub>, <sub>2C</sub> sites (i.e., HTR1A, 1B, 1E; HTR2A, 2C) that map to widely separated loci in the genome (chromosomes 5q11.2-q13, 6q13, 6q14, 13q14, and Xp24, respectively).

5-HT<sub>1A</sub> sites are numerous in limbic and frontal regions, but less abundant in the basal ganglia. While in the forebrain 5-HT<sub>1A</sub> sites are often postsynaptic, in the midbrain they more usually have a presynaptic location (Sharma and Shapiro, 1996). In contrast, 5-HT<sub>1B</sub> sites have a marked fronto-striatal distribution and are usually located presynaptically. Stimulation of either site can have disinhibitory effects that can, for example, enhance the release of dopamine (Millan *et al.*, 2007). 5-HT<sub>2A</sub> binding sites at pre- and postsynaptic loci are widely but differentially distributed through forebrain regions, with the highest density in frontal areas (Rosel *et al.*, 2002). They can exert a phasic, excitatory influence on catecholamine release from terminal regions, whereas 5HT<sub>2C</sub> receptors exert a tonic, inhibitory influence, usually at somatic loci (Millan *et al.*, 2007). Thus, the 5-HT<sub>1B</sub> and 5-HT<sub>2A</sub> receptors tend to be 'stimulatory' while the 5-HT<sub>1A</sub> and 5HT<sub>2C</sub> sites are more often 'inhibitory' (Martin *et al.*, 1998). Surprisingly little is known about 5-HT<sub>1E</sub> receptors, which make up a quarter of those binding 5-HT in the forebrain in *post-mortem* studies of cortical and hippocampal regions (especially the CA4 division; Barone *et al.*, 1994).

Historically, genetics studies of ADHD concentrated first on the HTR1B gene. As might be expected from the last paragraph, early studies with mice showed that activation of this site was associated with aggression and motor activity (Sandou *et al.*, 1994). However, it is not surprising (continuing the above line of discussion) that it was soon shown that knockout of this gene in mice affected attention-related (sensory gating) and reward-related

behavior (Dulawa *et al.*, 1997; Barot *et al.*, 2007). Thus, HTR1B seems to be implicated in three dimensions of responsiveness relevant to ADHD (attention, reinforcement and motor organization). Work with ADHD patients implicated more or less significantly sites in or around the HTR1B locus (e.g., the 861G allele) in the disorder (Hawi *et al.*, 2002; Quist *et al.*, 2003; Ogdie *et al.*, 2004; Smoller *et al.*, 2006; Ribases *et al.*, 2007). Despite this combined effort on some 1188 families, four research groups were then unable to replicate the results with a further 953 cases (Bobb *et al.*, 2005; Li *et al.*, 2005; Heiser *et al.*, 2007; Ickowicz *et al.*, 2007). Indeed, the IMAGE study of 776 ADHDct cases that used 11 different SNPs from the HTR1B gene could report no significant association (Brookes *et al.*, 2006). It is easy to qualify the results of each study, be they positive or negative, in a way that is suggestive of a subgroup of ADHD cases that may usually show an association with HTR1B. For example, the report of Smoller *et al.* (2006) emphasized paternal transmission, especially in cases of the inattentive subtype. The study of Li *et al.* (2005) was restricted to Han Chinese subjects. However, the hypotheses that can be developed regarding the diagnostic subtype or demographic stratification from such qualifications still await testing.

Despite an early report that HTR1A, along with TPH1 and 5-HTT, contributed to more than 3 percent of the variance in ADHD (Comings *et al.*, 2000), markers for this receptor have received little attention. Ribases *et al.* (2007) included SNPs covering this gene, but found no association with childhood or adult ADHD. However, it appears that HTR1E, which sits adjacent to HTR1B on chromosome 6, may soon elicit more concerted study. Although Ribases' group could report no significant findings, a nominally significant association was a novel finding in the IMAGE study of 674 families (Brookes *et al.*, 2006). Nominal significance also appeared in a genome-wide scan of the full IMAGE sample of 909 family trios (Lasky-Su *et al.*, 2008a). Separate analyses for phenotypes showing symptoms of aggressive impulsivity and cognitive impulsiveness in 1160 offspring from 590 families with an ADHD child revealed nominal associations for both phenotypes with an HTR1E SNP (Oades *et al.*, 2008). This SNP was under-expressed in behavioral impulsivity, but over-expressed in cognitive impulsiveness.

A link with aggressive behavioral impulsivity is more firmly established for increased 5-HT<sub>2A</sub>, decreased 5-HT<sub>1A</sub> receptor binding and low levels of 5-HT activity (Coccaro *et al.*, 1997; Parsey *et al.*, 2002; Carver and Miller, 2006). An early report of preferential transmission of the 452Tyr rather than the T102C polymorphism of HTR2A (Quist *et al.*, 2000) has not been confirmed using various methods (Hawi *et al.*, 2002; Galili-Weisstub and Segman,

2003; Bobb *et al.*, 2005; Guimaraes *et al.*, 2007; Heiser *et al.*, 2007). However, one case-control study of the T102 polymorphism did describe a highly frequent transmission of the T and a far less frequent transmission of the C allele (Su *et al.*, 2004). Yet in healthy subjects it has been suggested that the C allele is associated with *hyperactivity and impulsivity* (Reuter *et al.*, 2006). This complements the study of Ribases *et al.* (2007), above, that described an association for an SNP in HTR1D with *inattentive* cases of ADHD. Intriguingly, symptoms of hyperactivity and impulsivity were markedly inversely related to the age of onset in the IMAGE sample, which, in the genome-wide scan, was nominally associated with two HTR2A polymorphisms (Lasky-Su *et al.*, 2008b). While it is difficult to weigh up the evidence for and against an involvement of the determinants of 5-HT<sub>2A</sub> receptor in ADHD, one should not overlook that these reports made use of a variety of methods and are not always directly comparable. Further, having noted the involvement of 5-HT<sub>2A</sub> activity with impulsive aggression, it must be emphasized that recruitment rarely considers the nature and degree of co-morbidity. It is therefore salutary to see that, in a family-based association test of three measures of conduct problems, a categorical diagnosis was quite strongly associated ( $P = 0.0008$ ) with a marker for HTR2A on chromosome 13 in the IMAGE sample (Anney *et al.*, 2008b).

There have been few attempts to see if other 5-HT receptors could be involved in ADHD. Interest in the 5-HT<sub>2C</sub> site derives from its usually inhibitory interactions with the mesostriatal and mesolimbic dopamine systems: blockade of this interaction in rodents can lead to hyperlocomotion (Stiedl *et al.*, 2007) and cognitive impulsivity (Robinson *et al.*, 2008). An examination of several HTR2C haplotypes in a Chinese sample was able to demonstrate both over- and under-expression in different cases, with biased transmission occurring in those with ADHDct rather than ADHDia (Li *et al.*, 2006a). This research group has also reported equivocal results favoring the involvement of HTR4 polymorphisms, but a marked absence of any effects for HTR5A or HTR6 markers (Li *et al.*, 2006b, 2006c). Markers for the 5-HT<sub>4</sub> receptor deserve further attention, as activation in the rodent model facilitates aspects of cortical and limbic processing where knockout animals show impaired responses to novelty and cognitive challenge, potentially modeling aspects of the ADHD phenotype (Micale *et al.*, 2006).

It seems that receptors of both the 5-HT<sub>1</sub> and 5-HT<sub>2</sub> families can be associated with the disorder in some patients exhibiting ADHD, especially where the emphasis of the disorder is on externalizing features. Together these reports may be taken to point towards the role of co-morbid conduct problems, but also that the variability

of the results may reflect that the availability of 5-HT through the activity of synthesis and breakdown may influence the expression of some variants for the 5-HT receptors. Further study of the subtypes of 5-HT receptors is imperative.

## Neurotransmitter activity and functional associations

### Biochemical signs of activity

A number of laboratories have reported on peripheral measures of 5-HT or its metabolites, even though there is wide agreement that most of what is measured derives from somatic sources. Thus, the actual levels recorded are distant reflections of CNS activity. Nonetheless, if there were any deleterious influences on the control of 5-HT metabolism, these could affect both central and peripheral systems and potentially incur psychopathological consequences. Perhaps a more serious argument against the general usefulness of such measures is the great sensitivity of monoamine systems to the state and to the stage of development of the child (Oades *et al.*, 1996a). These features, along with the numerous co-morbid conditions of the patients, all prove very difficult to control adequately (discussion: Oades, 2007).

Reports on the levels of 5-HT and its major metabolite 5-hydroxy-indoleacetic acid (5-HIAA) in the urine, blood (plasma, serum, platelets) and cerebrospinal fluid (CSF) of healthy children and those with ADHD have been reviewed in detail (Oades, 2005). While some larger samples reporting decreased levels of 5-HT, many smaller studies found no differences. 5-HIAA levels have been more rarely studied. Perhaps surprisingly, even using measures from the CSF of children with ADHD, with healthy and conduct disordered children for comparison, no group differences were found (Castellanos *et al.*, 1994). The only reports on both 5-HT and 5-HIAA described an increased 5-HT metabolism in 24-hour urine samples taken from children with ADHD (Oades and Müller, 1997; Oades *et al.*, 1998), which is consistent with the reports (above) of decreased 5-HT excretion. Also in accord with this finding, it has been reported that treatment with a psychostimulant resulted in marked decreases of catecholamine metabolites, 5-HIAA and platelet MAO activity (Uzbekov, 2006).

### 5-HT activity and functional associations

Studies of groups of ADHD children may fail to provide unequivocal associations with the general levels of 5-HT activity measured. Nonetheless, there may remain

dimensional relationships for these measures with the expression of various traits across individuals that reflect some of the genetic features of 5-HT discussed above. For example, an association of an MAOA allele with the degree of cognitive impulsivity shown by ADHD children was described in the previous section (Manor *et al.*, 2002). Thus, while no gender or group differences in the 5-HT uptake by blood platelets could be found in a sample of 84 girls and boys with ADHD aged 4–14 years (Novkovic *et al.*, 2009), the 5-HT levels in the platelets were much higher in those with marked impulsive symptoms. The same result has been reported for a small group of impulsive adolescents (Askenazy *et al.*, 2000).

Measures of the uptake of 5-HT by blood platelets model well the transport mechanisms in brain tissue (Lesch *et al.*, 1993) and thus merit attention in the study of ADHD. The affinity of this uptake site in 20 children with ADHD was measured with paroxetine and shown to correlate with different aspects of impulsivity (Oades *et al.*, 2002). Increases of affinity (but not of the  $B_{\max}$  measure of density) related to ratings of impulsive aggressive behavior. In contrast, though, decreases of affinity were related to the ability on a stop-task to attend to stimuli requiring the children to withhold response after they had received a 'Go' stimulus. This attention-related ability in turn correlated well with ratings of distractibility and impulsivity. The context here of two sorts of impulsivity with different associations with 5-HTT affinity supports the description above of modest small effects of alleles influencing synthesis (TPH2), uptake (5-HTT) and synaptic effect (HTR1E) in ADHD that was also dependent on the predominant type of impulsiveness (Oades *et al.*, 2008).

An alternative method for registering the status of the 5-HT system (in particular receptors belonging to the 5-HT<sub>2</sub> family) is to register the responsiveness of prolactin to a challenge dose of a drug. In the context of the control of behavioral impulsivity, it is of interest to note that poor responsivity to a challenge with fenfluramine as a child (aged 7–11 years) was reported to be associated with aggression and antisocial behavior 6–7 years later as an adolescent (Halperin *et al.*, 2006; Flory *et al.*, 2007). In contrast to the role of 5-HT<sub>2</sub> receptors in facilitating aggressive traits, animal work has clearly emphasized the role of receptors of the 5-HT<sub>1</sub> family in non-aggressive impulsivity. For example, administration of 5-HT<sub>1A</sub> agonists to rats was noted to enhance impulsiveness in delayed discounting tasks (Winstanley *et al.*, 2005). While there is unfortunately no directly comparable study with ADHD children who have problems in awaiting reinforcement, there is evidence from the use of a challenge dose of a 5-HT<sub>1D</sub> agonist with oppositional children showing ADHD symptoms (Snoek *et al.*, 2002). In terms of the amount of growth hormone release elicited by this drug,

receptors in these children were twice as sensitive as those in a healthy comparison group. This could provide a basis and consequence for the cognitive impulsivity, described in the genetics section, where there is an indication for over-expression of the HTR1E site. Animal studies indicate the potential effect in practice. On choice reaction time tasks, the impulsive errors of commission made by rodents were reported to correlate with 5-HT release in frontal regions, as measured by microdialysis (Dalley *et al.*, 2002). Interestingly, this over-responsiveness could be blocked by administering 5-HT<sub>2A</sub> antagonists, thus indicating the way the 5-HT system can exert opposing influences on two forms of impulsivity.

Potentially, the anomalous activity in the 5-HT system in those with ADHD may affect information processing from sensory input and perception through attention to learning and memory (see Chapter 3.9 of this volume). For example, in the auditory system 5-HT innervation and activity is marked in the cochlea (Doleviczenyi *et al.*, 2008) and the primary auditory cortex (Jacobs and Azmitia, 1992). It should not surprise, then, that d-prime, a signal detection marker of perception measured on a continuous performance task, was associated – indeed was correlated negatively with – excretion of 5-HIAA in children with ADHD (Oades, 2000). Later in processing, the selective aspects of attention documented by conditioned blocking were also influenced. Here, the normal ability to restrict attention and not learn about redundant conditioned stimuli was correlated positively with 5-HT metabolism (Oades and Müller, 1997). This association was the opposite to that obtained for children with the tic syndrome. These data suggest how 5-HT metabolism is associated with enhanced target processing and restricted distractor processing in ADHD.

### 5-HT activity and neurophysiological recording

In this section, some examples of the potential interaction of 5-HT activity with such stimulus processing, namely 'event-related processing', are considered from records of the EEG. Salient stimuli elicit a negatively-directed event-related potential (ERP) in the EEG (the N1) after about 100 ms and shortly thereafter a positively-directed component (the P2) that reduces the influence of other stimuli competing for processing. The combined N1–P2 amplitude can depend on the loudness of an auditory stimulus. In 'augmenters' it increases with loudness and the slope of the amplitude–intensity relationship becomes steeper; 'reducers' it decreases and the slope becomes flatter. Early studies of those with 'ADHD', using earlier diagnostic criteria, showed that putative combined types were more likely augmenters than putative inattentive

types or healthy controls (Buchsbaum and Wender, 1973; Dykman *et al.*, 1983). The augmenting response correlates with the sort of behavioral impulsivity that reflects decreased 5-HT activity (Hegerl *et al.*, 1992).

Studies of the ERP and its tangential dipole in the primary auditory cortex, which receives a dense 5-HT innervation (Azmitia and Gannon, 1986), indicate that a steep slope correlates with low 5-HT and high 5-HIAA levels and *vice versa*. This was deduced from the effects of challenges with drugs that have agonistic or antagonistic effects on the 5-HT system (e.g., lithium, alcohol, zimelidine, fenfluramine; Hegerl and Juckel, 1993, 1994). Studies of the similar phenomenon in rats following administration of the uptake inhibitor citalopram (Wutzler *et al.*, 2008) or in cats after treatment with a 5-HT<sub>1A</sub> agonist (8-OH-DPAT) described decreased intensity dependence, while there was increased intensity dependence after administering the 5-HT<sub>2</sub> antagonist ketanserin (Juckel *et al.*, 1997, 1999). In humans, support for the locus of the effect (primary auditory cortex) has come from fMRI studies (Mulert *et al.*, 2005), and for the 5-HT involvement from genetics. In this instance, homozygotes for the high-activity, long allele of the 5-HTT promoter exhibit weaker intensity dependence than heterozygotes (Gallinat *et al.*, 2003). The problems are that (1) others have found that the long allele related more to a stronger intensity dependence (Strobel *et al.*, 2003; Hensch *et al.*, 2006); (2) acute depletion of tryptophan with an amino-acid drink did not clearly influence intensity dependence (Dierks *et al.*, 2000; Debener *et al.*, 2002; O'Neill *et al.*, 2008a); and (3) intensity dependence is not sensitive to challenge from all drugs influencing 5-HT metabolism (O'Neill *et al.*, 2008b). Resolution of the controversy is not simple, because (1) the long allele of the 5-HTTLPR consists of two alleles (A and G) with stronger and weaker effects in this paradigm (Gallinat *et al.*, 2007); (2) the various studies report using different stimulus intensities and degrees of 5-HT depletion after tryptophan drinks; and (3) extensive drug testing has usefully highlighted the additional contribution of other neurotransmitters (e.g., dopamine) to loudness dependency (Nathan *et al.*, 2005). Direct investigation of these parameters in those with a diagnosis of ADHD would be useful. Nonetheless, an influence of 5-HT activity on loudness dependency and in particular on early stimulus processing in those with ADHD seems likely.

If one accepts that the N1–P2 peak to peak amplitude is influenced by 5-HT activity, it is a small step to propose that the same activity underlies the frequent appearance of a larger P2 amplitude in oddball discriminations in those with ADHD than is normal (Oades, 2006). This has been reported for the childhood (Satterfield *et al.*, 1984; Oades *et al.*, 1996b; Johnstone *et al.*, 2001) and the adult condition (Barry *et al.*, 2009). The next inhibitory ERP

after the P2 is the P3, which reflects the need to update a working-memory-like template following stimulation and the effort required to do this. This component is usually recorded from posterior scalp regions, and may have its origin in several brain regions. These sources apparently differ between straightforward discriminations and a go/no-go task where withholding a response elicits a marked 'P3' that is normally more anteriorly located in frontal regions. The presence of alleles for the TPH2 gene that are considered a risk for ADHD alters the topography of this component, and thus implies an important role for 5-HT modulation of the response (Baehne *et al.*, 2008). This was reported to hold for adult carriers of the respective SNPs independent of whether they had a diagnosis of ADHD or were considered healthy.

Finally, there is a sequence of ERPs that can be recorded if the 'event' is the response rather than the stimulus. This is of special interest where the response is an error. In this case it is followed by a component called the error-related negativity (ERN). Studies of ERN in ADHD patients have yielded disparate results in the eight studies published so far, largely due to the broad developmental age range of the subjects, the presence of variable co-morbid problems and the use of different tasks to produce errors. However, half the reports with young patients which usually used a modified Eriksen flanker task found the ERN to be more or less reduced (Liotti *et al.*, 2005; Van Meel *et al.*, 2007; Albrecht *et al.*, 2008; Groen *et al.*, 2008; Wild-Wall *et al.*, 2009). Independent of the proposed involvement of the dopaminergic system in modulating the ERN (Holroyd and Coles, 2002), 5-HT activity likely also plays a role (Jocham and Ullsperger, 2008). Healthy young adults with one or two copies of the low-activity, short allele variant of the 5-HTT promoter showed much larger ERN amplitudes than age- and gender-matched subjects homozygous for the long allele (Fallgatter *et al.*, 2004). Where ADHD cases carry the long allele (Seeger *et al.*, 2001; Curran *et al.*, 2005), a smaller ERN may be anticipated (Figure 2).

In conclusion, there is evidence from neurophysiological recording studies, as with the previous section, that 5-HT activity can influence processes ranging from perception, through attention to learning. There is evidence at each level of processing for anomalies relating to 5-HT responsivity in ADHD. If the evidence is sometimes circumstantial, this section points to the sorts of study needed to validate these claims.

### 5-HT activity and neuroimaging

One direct way to demonstrate 5-HT involvement in the problems of ADHD children would be to examine ligand

**Figure 2** Response-locked grand-averaged event related potentials (ERP). (Left) Comparison between the ERPs of correct (thin line) and incorrect (bold line) responses of 11 subjects with one or two copies of the low-activity short 5-HTTLPR variant. (Right) Comparison between the ERPs to correct (thin line) and incorrect (bold line) responses of 11 subjects homozygous for the long allele. Adapted by permission from Macmillan Publishers Ltd, (*Neuropsychopharmacology*, Fallgatter *et al.* 2004).

binding with PET. This form of study is difficult to carry out with children for ethical reasons, and hence there are only two reports with some relevance. 5-HTT binding ( $^{123}\text{I}$ -FP-CIT) in the midbrain and brainstem of adult ADHD patients was examined using SPECT methods (Hesse *et al.*, 2006). The authors were unable to report any unusual binding characteristics. However, another study in children with fetal alcohol syndrome, who all showed ADHD, used the  $^{123}\text{I}$ -labeled nor-CIT as a specific label for 5-HTT (Riikonen *et al.*, 2005). The report described significantly less binding (25 percent) in the anterior cingulate cortex, but no alteration in the temporal lobe or midbrain. It would be useful to seek direct evidence for the role of 5-HT either with a pharmacological fMRI paradigm (the uptake inhibitor venlafaxine has been successfully used with adult patients) or with subjects expressing genotypes with known effects on 5-HT metabolism (e.g., 5-HTT or MAO alleles).

Let us briefly consider indirect evidence for proposing that parts of the frontal cortex (as indicated above) would provide interesting target areas for study, and first look at the more ventral regions. Gray- and white-matter reductions in the orbito-frontal cortex have been reported in adolescents with or at high risk for ADHD (van t'Ent *et al.*, 2007; Huebner *et al.*, 2008) as well as adults with ADHD (Hesslinger *et al.*, 2002). The data emphasize impairment in the left hemisphere. In contrast, prominent conduct problems were associated more with anomalies in limbic regions. However, the connectivity of orbito-frontal with limbic regions (Plessen *et al.*, 2006) or between the hemispheres (over the rostral corpus callosum) may also be compromised (Giedd *et al.*, 1994). Although an earlier report on children with ADHD was not supportive (Hill *et al.*, 2003), half the subjects showed

an oppositional disorder that may have reflected developing conduct problems.

The orbito-frontal cortex receives a marked 5-HT innervation, and genetic variants of MAOA and 5-HTT exert a clear influence on 5-HT activity in orbito-frontal regions (Carver and Miller, 2006; Meyer-Lindenberg *et al.*, 2006; Passamonti *et al.*, 2006; Way *et al.*, 2007). Activation in MRI scans of orbito-frontal regions has been related to features typical of ADHD patients, albeit in non-ADHD subjects. These features include response inhibition abilities and ratings of impulsivity from the Eysenck and Barratt scales (Horn *et al.*, 2003). Damage to these regions impairs delayed discounting as a measure of motivationally influenced impulsivity (Kalenscher *et al.*, 2006). Under-activation of orbito-frontal (and anterior cingulate) regions, illustrated by fMRI, is associated with errors of commission in a continuous performance task, a measure of cognitive impulsivity (Casey *et al.*, 1997). Reduced bilateral orbito-frontal activation during sustained attention was confirmed as specific to ADHD children without co-morbidity, and contrasted with a sample exhibiting pure conduct disorder who were only impaired in a second condition associated with reward (Rubia *et al.*, 2008a).

Not only ventral, but also more dorsal and lateral frontal regions are prominent in the circuitry that has been reported to be underactive in ADHD children performing a go/no-go task (Durston *et al.*, 2006). In addition, the study found that siblings of these cases also showed reduced activity in these regions, implying a genetic influence on their ability to activate prefrontal regions when appropriate. Similarly, inferior- and mid-frontal regions were reported to be under-activated in ADHD cases during errors or even successful inhibition of responses on

go/no-go and stop-tasks (Rubia *et al.*, 2005, 2008b; Smith and Taylor, 2006). The effects were seen bilaterally, with an emphasis on the right hemisphere, and correlated with symptom ratings. This lack of appropriate activation will be reflected in processing impairments in connected brain regions, as was shown by impaired fractional anisotropy in fiber tracts in right prefrontal areas (Casey *et al.*, 2007). These results were obtained with ADHD children, but were reported to be tightly associated with findings from their parents, again implying a familial if not a genetic link. The potential involvement of 5-HT activity here is indicated by a study of the effect of acute tryptophan depletion that likely suppressed 5-HT synthesis in the healthy young adults studied (Rubia *et al.*, 2004). Regional frontal activation shown with fMRI during a go/no-go task was specifically reduced in the right inferior frontal and orbito-frontal regions, as recorded for ADHD patients (above).

This section has taken only the frontal cortices for consideration of their role in ADHD, and described the likelihood that this role is influenced by 5-HT activity. Earlier sections focused on 5-HT in the thalamus and the temporal lobe, which reflect important afferent and efferent connections of the frontal regions discussed here. It is not difficult to point out additionally the importance of function (and apparent dysfunction in ADHD) of fronto-striatal and fronto-parietal processing to planning and execution of responses in which 5-HT exerts marked interactions with the catecholamine innervation and glutamatergic mediation of activity.

## Conclusions

The genetic contributions to the high heritability (76 percent; Faraone *et al.*, 2005) of ADHD are under active investigation. Part of the variance is explained by modest contributions of a range of genes with small effect. Some of these influence catecholaminergic neuromodulators, growth factors and development, and among these, some affect the 5-HT system. The initial evidence so far is controversial in detail, but points to a combined role for genes influencing the availability of extra-neuronal 5-HT (i.e., primarily synthesis, breakdown and re-uptake and secondarily the receptor mediating and controlling function). A differential or combined role is evident for subtypes of the disorder, especially with respect to the variable expression of impulsivity and conduct problems. The evidence does not speak for a single process for the full disorder. The normal functions affected range from perception, to attention to learning and related emotional/motivational moderation of function. Memorial and motor mechanisms still require study. The problems that those with ADHD

have in the laboratory, the clinic, at home and in the world at large are only partly ameliorated by current treatments that concentrate on catecholaminergic function, and some cases do not respond to such treatments. More attention to the widespread involvement of 5-HT in all the domains of function affected in ADHD should lead to an understanding of the disorder that can only benefit the development of even more effective treatments.

# Serotonin and Schizophrenia

Boris B. Quednow<sup>\*,1</sup>, Mark A. Geyer<sup>2</sup> and Adam L. Halberstadt<sup>2</sup>

<sup>1</sup>University Hospital of Psychiatry, University of Zurich, Switzerland

<sup>2</sup>Department of Psychiatry, University of California at San Diego, California

**Abstract:** Although the serotonin hypothesis of schizophrenia is one of the oldest neurochemical hypotheses on the pathogenesis of this disease, it is still highly topical. The concept of how the serotonin system is involved in the origin and progress of schizophrenia has considerably changed over the past decades. Therefore, the present work will give an overview about the development and the current directions of the serotonin hypothesis of schizophrenia. In this regard, we will discuss the phenomenology of hallucinogenic drug action, model psychosis and translational research, *post mortem* studies on receptors and transporters, imaging studies, antipsychotic drug action, neuroendocrine challenge studies, platelet and cerebrospinal fluid data, genetic association studies, developmental aspects, and the cross-talk between the glutamate and the serotonin system. In sum, there are several lines of evidence suggesting that the serotonin system plays a major role in the pathogenesis of at least a subpopulation of schizophrenia patients. Further studies are needed to better characterize patients whose psychotic symptoms are suspected to have a serotonergic origin.

**Keywords:** serotonin, 5-HT, schizophrenia, model psychosis, LSD, psilocybin, atypical antipsychotics, 5-HT<sub>2A</sub> receptor, platelets, positron emission tomography, single nucleotide polymorphism, developmental disorder, dopamine, glutamate, cognition.

## Introduction

The symptoms of schizophrenia can be divided into three major domains: (1) positive symptoms such as hallucinations, perceptual disturbances, delusional phenomena and formal thought disorder; (2) cognitive dysfunction, which includes motivational and executive function deficits; and (3) negative symptoms, including flat affect, poverty of speech, avolition and inappropriate emotional responses (Tamminga and Holcomb, 2005). Presentation of symptoms from these three domains is heterogeneous, making the illness difficult to diagnose and treat. The highest risk period for developing schizophrenia is during young adulthood. Both sexes are equally affected by the disorder, although the age of onset of symptoms is typically younger for men than women (Goldstein *et al.*, 1989; Faraone *et al.*, 1994; Bromet and Fennig, 1999). Although incidence figures vary depending on the diagnostic criteria, schizophrenia affects approximately 1 percent of the general population. Individuals with schizophrenic parents or siblings have an increased risk for developing the illness (8–12 percent). For monozygotic twins, the

concordance rate is approximately 50 percent (Holzman and Matthysse, 1990; Gottesman, 1991). The elevated familial incidence of schizophrenia strongly indicates that there is a genetic contribution to the disorder, although the fact that concordance rates for monozygotic twins are lower than 100 percent suggests that environmental factors are also involved. It is therefore likely that a combination of genetic susceptibility and environmental factors is required for the illness to develop (Gottesman, 1991). Linkage studies of schizophrenia have identified several chromosomal regions and candidate genes that are associated with the disorder (reviewed by Harrison and Owen, 2003; Harrison and Weinberger, 2005).

Although there is evidence for enlarged ventricles and decreased cerebral (cortical and hippocampal) volume associated with schizophrenia, there is not a distinct ‘diagnostic’ neuropathology associated with the disease (reviewed by Harrison, 1999a, 2004; Harrison and Owen, 2003). Misplaced and clustered neurons, particularly in the entorhinal cortex, indicate problems of neuronal migration, and suggest an early developmental anomaly (Jakob and Beckmann, 1986; Arnold *et al.*, 1991; Falkai *et al.*, 2000). Pyramidal neurons in the hippocampus and neocortex have been shown to have smaller cell bodies and fewer dendritic spines and dendritic

\*Corresponding author  
E-mail: quedenow@bli.uzh.ch

arborizations (reviewed by Harrison and Weinberger, 2005). Additionally, decreased presynaptic proteins such as synaptophysin, SNAP-25 and complexin II have been observed in schizophrenia brains (Harrison and Eastwood, 2001; Honer and Young, 2004), as well as decreased density of interneurons (e.g., parvalbumin-immunoreactive cells; Lewis, 2000; Reynolds *et al.*, 2002a). There are also reports of decreases in cell numbers in the thalamus and a decreased number of oligodendrocytes. Neuroimaging data and *post mortem* studies have shown that N-acetylaspartate (NAA), a marker of neuronal integrity, is decreased in first-episode and never-medicated patients (Bertolino and Weinberger, 1999; Nudmamud *et al.*, 2003). Based on these neuropathological changes, investigators have conceptualized schizophrenia as a disease of functional 'dysconnectivity' (Weinberger *et al.*, 1992; Friston and Frith, 1995; McGlashan and Hoffman, 2000), or a 'disorder of the synapse' (Mirmics *et al.*, 2001; Frankle *et al.*, 2003) affecting the machinery of the synapse (Harrison and Eastwood, 2001; Honer and Young, 2004).

Not only structural alterations but also neurochemical changes have been proposed to play a role in the etiology of schizophrenia. In the following sections, we give an overview on the serotonin hypothesis of schizophrenia. Although it is one of the oldest neurochemical hypotheses on the pathogenesis of this disease, it is still highly topical, as will be shown in the following sections.

### History of the serotonin hypothesis of schizophrenia

The first step in the direction of the idea that the serotonin system may contribute to schizophrenia was probably made by the German psychiatrist Kurt Beringer (1923). He was the first to propose the use of the hallucinogen mescaline as an experimental model of psychosis, despite the fact that he had no knowledge of serotonin receptors or the principles of neurotransmission. Previously, on the eve of World War I, Knauer and Maloney (1913) had already recommended the mescaline self-experience for psychiatrists to gain better insights into the psychotic states of their patients. Subsequently, we have come to understand that mescaline is a selective serotonin-2A (5-HT<sub>2A</sub>) receptor agonist that played an important role in the development of the transmethylation hypothesis of schizophrenia. In 1943, Albert Hofmann identified the impressive psychotomimetic effects of d-lysergic acid diethylamid (LSD) during an unintentional self-intoxication in his laboratory at Sandoz Pharmaceutical Company (Stoll, 1947). During subsequent repeated self-experiments, Hofmann noted that the necessary dose

of LSD to cause psychological effects was very small, strongly suggesting that there must be a receptor or some other specific site of action for the LSD molecule. Mescaline, in contrast, had to be given in hundreds of milligrams to produce psychotomimetic effects that were comparable to the effects of several micrograms of LSD (Stoll, 1947). Hofmann gave LSD to Walter Stoll, a psychiatrist at the University Hospital of Psychiatry Zurich 'Burghölzli', and the son of Hofmann's supervisor Arthur Stoll at Sandoz. The younger Stoll explored the psychopathological effects of LSD in 16 healthy volunteers and found that the LSD effects were strikingly similar to the symptoms of schizophrenia (Stoll, 1947).<sup>1</sup> Subsequently, both Stoll and his colleague Condrau administered LSD to patients with schizophrenia, hoping that the LSD 'shock' may have some therapeutic benefits. They noted that LSD is much less potent in schizophrenia patients than in normal controls, and therefore concluded that a toxic substance similar to LSD may cause schizophrenic psychoses (Stoll, 1947, 1949; Condrau, 1949). With this perception, they paved the way for the transmethylation hypothesis. Moreover, both authors noted that LSD may prove to be a valuable tool to induce psychotic states experimentally in the laboratory.

While searching for a vasoconstrictive substance in platelets, Rapport and colleagues (1948) discovered serotonin; soon thereafter, the structure of serotonin was deduced (Rapport, 1949). Betty Twarog and Page (1953) subsequently demonstrated that serotonin could be found in the mammalian brain. Initially it was thought that serotonin was simply a residue of blood in the brain, but the structural similarities between LSD and serotonin led to the suggestion that serotonin may act directly in the brain (Healy, 2002). Gaddum (1953) quickly determined that the oxytocic effects of serotonin could be antagonized by LSD. As was fashionable at the time among pharmacologists, Gaddum took LSD himself. The intense experience encouraged him to propose that serotonin in the brain may play a role in preserving sanity (Gaddum and Hameed, 1954; Healy, 2002). At the same time, Woolley and Shaw (1953) independently discovered that other centrally acting indoleamines (yohimbine, ergot alkaloids, harmine) also antagonize the vasoconstrictive action of serotonin, and they also concluded that serotonin may play a role in nervous disorders (Woolley and Shaw, 1954). Gaddum and Hameed (1954) and Woolley and Shaw (1954) proposed that serotonin activity might be decreased in the brain of schizophrenia patients. Subsequent evidence indicating that LSD is an agonist rather than an antagonist

<sup>1</sup> Interestingly, Stoll (1947) had already suggested radioactive labeling of LSD to investigate, in animals, which brain regions LSD acts upon.

questioned this hypothesis (Baumeister and Hawkins, 2004). Later, Woolley (1962) revoked his initial suggestion and stated that schizophrenia may result from an excess of brain serotonin.

Shortly before the discoveries of Gaddum, Woolley and Shaw, another serotonin-related hypothesis of schizophrenia had also appeared. As early as 1932, Henk de Jong noted that mescaline is chemically related to epinephrine. He therefore supposed that a disturbance of epinephrine metabolism might lead to the synthesis of a mescaline-like substance that causes catatonia, one of the primary forms of schizophrenia at that time (de Jong, 1932). Twenty years later, Osmond and Smythies (1952) reinvented this idea and proposed the influential transmethylation hypothesis of schizophrenia. Osmond and Smythies observed that an asthmatic patient developed psychotic symptoms after he had taken old (and therefore oxidized) epinephrine during an asthmatic attack. In a self-experiment, Osmond and his director Abram Hoffer then took adrenochrome – a breakdown product of epinephrine, pink in color – and reported that it produced hallucinogenic responses (Healy, 2002). These observations led to their assumption that schizophrenia results from an endogenous neurotoxin that is formed by aberrant metabolic processes during the biosynthesis of catecholamines. The last step of the biosynthesis of epinephrine is methylation of the amino group of norepinephrine. If the phenolic hydroxyl groups were irregularly methylated instead, then a mescaline-like compound would be produced. Later Hoffer, Osmond and Smythies (1991) expanded the transmethylation hypothesis by proposing the possibility of an aberrant endogenous biosynthesis of methylated indolamine hallucinogens such as LSD. In the following years, many researchers tried to find the ‘pink spot’ of adrenochrome and other suspected endogenous neurotoxins in the brain, blood or urine of schizophrenia patients; however, it was never convincingly found. Moreover, Hoffer and Osmond brought their theory directly to the clinic and treated schizophrenia patients with large doses of nicotinic acid because it acts to trap methyl donors, and thus the aberrant transmethylation of catecholamines or indolamines should be decreased. The authors reported that nicotinic acid alone, as well as in combination with chlorpromazine, had some beneficial effects in the treatment of schizophrenia, but these results could not be replicated in later studies performed by the Canadian Association of Mental Health (Healy, 2002). Although the transmethylation hypothesis still has strong face validity, it fell out of favor after the 1960s for two reasons: first, the schizophrenogenic substances could not be isolated; and secondly, a new influential theory targeting another neurotransmitter commandeered the focus of schizophrenia research. For the time being, the serotonin

hypotheses were superseded by the influential dopamine hypothesis of schizophrenia.

### The dopamine hypothesis of schizophrenia

Based on the finding of Brodie *et al.* (1955, 1956) that reserpine acutely releases brain serotonin while post-acutely depleting it, the group of Arvid Carlsson demonstrated that reserpine has the same effect on catecholamines (Bertler *et al.*, 1956). These results suggested that serotonin and catecholamines may play a role in the sedative and motor-depressant effects of reserpine. Carlsson *et al.* (1957) tested this hypothesis by administering the precursors L-dopa and 5-hydroxytryptophan to animals after a pre-treatment with reserpine. Only L-dopa attenuated the behavioral effects of reserpine, whereas 5-hydroxytryptophan had no effect. Subsequently, it was shown that L-dopa increases brain dopamine but not norepinephrine (Carlsson, 1959). These results suggested an important role of dopamine in brain function. In 1963, Carlsson and Lindqvist reported that chlorpromazine and haloperidol reduced catecholamine activity through a postsynaptic action (Carlsson and Lindqvist, 1963). Later, van Rossum (1966) explicated that blockade of postsynaptic dopamine receptors is responsible for the behavioral effects of these neuroleptic drugs. The dopamine hypothesis of schizophrenia – which is actually a hypothesis of neuroleptic drug action – was born. For more than three decades, the dopamine hypothesis has dominated biological research on the etiopathogenesis of schizophrenia. The assumption that schizophrenia is caused by a significant disturbance of dopamine transmission (or metabolism) that results in an increase of dopamine function was initially supported by the following data (Bleich *et al.*, 1988):

1. All (admitted) antipsychotic drugs are dopamine-D<sub>2</sub> (D<sub>2</sub>) receptor antagonists, and before the advent of ‘atypical’ antipsychotics 20 years ago it was shown that antipsychotic potency of the neuroleptics was directly correlated with D<sub>2</sub> receptor binding (Meltzer and Stahl, 1976; Seeman, 1987). However, the latter is not true for clozapine, which is still the gold standard of antipsychotic drug action, because it has only a moderate affinity for D<sub>2</sub> receptors but higher affinity for 5-HT<sub>2A</sub>, 5-HT<sub>2C</sub>, 5-HT<sub>6</sub> and 5-HT<sub>7</sub> receptors, as well as for D<sub>4</sub>, histamine H<sub>1</sub>, muscarinic M<sub>1</sub>,  $\alpha_1$ , and  $\alpha_2$  receptors (Arnt and Skarsfeldt, 1998; Abi-Dargham and Krystal, 2000).
2. Sustained or high-dose exposure to indirect dopamine agonists (e.g., L-dopa, cocaine, amphetamine) may cause psychotic symptoms in healthy subjects that

are similar to those of paranoid schizophrenia (Segal *et al.*, 1981). Moreover, indirect dopamine agonists provoke exacerbation of symptoms in schizophrenia patients. Amphetamine is known to release presynaptic dopamine and norepinephrine, and it was shown that antipsychotics could improve the acute symptoms of amphetamine psychosis (Snyder, 1973; Carlsson, 1988). Nevertheless, psychotic states induced by indirect dopamine agonists mimic only the positive symptoms of schizophrenia; thus, maybe only the positive symptoms might be due to an increased dopaminergic activity (Angrist and Gershon, 1970).

3. *Post-mortem* studies and imaging studies with positron emission tomography (PET) initially indicate an increase of striatal D<sub>2</sub> receptor levels in the brains of schizophrenia patients (Wong *et al.*, 1986; Seeman, 1987). However, up-regulation of D<sub>2</sub> receptor expression could be the result of adaptation to antipsychotic drug treatment rather than a pathological abnormality inherent to schizophrenia, and in fact many *post-mortem* and PET studies could not replicate the finding of increased striatal D<sub>2</sub> receptor density in drug-naïve schizophrenia patients (Harrison, 1999a; Weinberger and Laruelle, 2002). However, there is accumulating evidence for a pre-synaptic dopaminergic abnormality in schizophrenia, implying disturbances in presynaptic storage, vesicular transport, release, reuptake and metabolic mechanisms in mesolimbic dopamine systems (Laruelle *et al.*, 1999; Weinberger and Laruelle, 2002).

The current view on the role of dopamine in schizophrenia is that subcortical mesolimbic dopamine projections might be hyperactive (causing productive symptoms) and that the mesocortical dopamine projections to the prefrontal cortex (PFC) and the anterior cingulate are hypoactive (causing negative symptoms and cognitive impairment). These two dysfunctions might be linked, as the cortical dopamine system generally inhibits the subcortical dopamine system (Weinberger and Laruelle, 2002).

Addressing the psychopathological heterogeneity of schizophrenia, Timothy Crow (1980a, 1980b) proposed that schizophrenia be divided into two syndromes: type I is characterized by positive symptoms that reflect an increase in striatal dopamine function, and responds well to antipsychotics; while type II is more characterized by negative symptoms, structural brain abnormalities (cortical atrophy and/or ventricular enlargement) and limited response to (typical) antipsychotics. Bleich *et al.* (1988) suggested that the type II syndrome might

respond better to serotonin antagonistic compounds, and thus he proposed a dopaminergic and serotonergic form of schizophrenia. This view is supported by the fact that some atypical substances having a strong 5-HT<sub>2A</sub> receptor antagonistic component may be superior in the treatment of negative symptoms when compared to typical neuroleptics without a strong serotonin antagonistic action (Meltzer, 1999). The fact that amisulpride, a pure D<sub>2</sub>/D<sub>3</sub> antagonist, has nevertheless a strong impact on not only positive but also negative symptoms may be due to its unique pharmacokinetic properties (Leucht, 2004).

## Phenomenology of hallucinogenic drug action

### *Effects of hallucinogens in human subjects*

Serotonergic hallucinogens produce profound alterations in thought, mood, affect and sensory perception. The effects of these drugs are often characterized by visual illusions and elementary hallucinations, altered sense of time and space, and depersonalization. Hallucinogen-induced Altered States of Consciousness (ASCs) are highly subjective, and are typically assessed using self-reports. Various rating scales have been used to assess the effects of hallucinogens (reviewed by Strassman, 1995). The Addiction Research Center Inventory (Haertzen *et al.*, 1963) is an older instrument that emphasized the unpleasant effects of hallucinogens. The Hallucinogen Rating Scale (HRS) was designed specifically to detect the effects of intravenous N,N-dimethyltryptamine (Strassman *et al.*, 1994), and has now been validated for other hallucinogens (Gouzoulis-Mayfrank *et al.*, 1999). Another rating scale, the Altered States of Consciousness Questionnaire (APZ), was developed by Dittrich to assess various types of ASCs, independent of their etiology (Dittrich, 1998). The original APZ includes three dimensions that have been labeled: Oceanic Boundlessness (OB), Anxious Ego Dissolution (AED) and Visionary Restructuralization (VR). The OB dimension measures states that resemble mystical experiences, the AED dimension reflects 'bad trip'-like experiences, and the VR dimension refers to altered visual perception. An updated version of the APZ, the 5D-ASC, includes two additional dimensions: Reduction of Vigilance (RV) and Auditory Alterations (AA). For a detailed description of the APZ and 5D-ASC core dimensions, see Table 1.

Clinical studies have demonstrated that psilocybin, DMT and mescaline increase scores in the OB, AED and VR dimensions of the APZ (Hermle *et al.*, 1992; Vollenweider *et al.*, 1997a; Dittrich, 1998;

**Table 1** Core dimensions of the 5D-ASC (Dittrich, 1998)

Dimension	Symptoms assessed
Oceanic Boundlessness (OB)	<i>Positive derealization</i> <i>Positive depersonalization</i> <i>Altered sense of time</i> <i>Positive mood</i> <i>Mania-like experience</i>
Anxious Ego Dissolution (AED)	<i>Anxious derealization</i> <i>Thought disorder</i> <i>Delusion</i> <i>Fear of loss of control</i>
Visionary Restructuralization (VR)	<i>Elementary hallucinations</i>  <i>Visual pseudohallucinations</i> <i>Synesthesia</i> <i>Changed meaning of percepts</i> <i>Facilitated recollection</i> <i>Facilitated imagination</i>
Auditory Alterations (AA)	<i>Auditory illusions</i> <i>Auditory pseudohallucinations</i>
Reduction of Vigilance (RV)	<i>Drowsiness</i> <i>Decreased alertness</i> <i>Impaired cognitive function</i>

Gouzoulis-Mayfrank *et al.*, 1999). Additional studies have shown that psilocybin produces a dose-dependent increase of scores in the five core dimensions of the 5D-ASC rating scale (Hasler *et al.*, 2004). However, AED and AA scores are increased significantly only after administration of a high dose of psilocybin (0.315 mg/kg, p.o.), and are relatively unaffected by lower doses (0.045–0.215 mg/kg).

A large amount of preclinical evidence indicates that the 5-HT<sub>2A</sub> receptor mediates most of the behavioral effects of hallucinogens. Pre-treatment with the 5-HT<sub>2A</sub> antagonist ketanserin blocks the effects of psilocybin on the APZ in human volunteers (Vollenweider *et al.*, 1998), confirming the involvement of the 5-HT<sub>2A</sub> receptor. According to a recent PET study with [<sup>18</sup>F]altanserin, the ability of psilocybin to increase 5D-ASC scores is directly correlated with the level of 5-HT<sub>2A</sub> receptor occupation in the anterior cingulate cortex and medial PFC (Hasler, Quednow, Vollenweider, unpublished data, Figure 1). These findings are consistent with those of an [<sup>18</sup>F]fluorodeoxyglucose PET study (Vollenweider *et al.*, 1997a), which found that the effects of psilocybin on the APZ are correlated with increases in PFC and anterior cingulate metabolic activity.

**Figure 1** Inverse Correlation of 5D-ASC Global Scale scores and [<sup>18</sup>F]altanserin apparent distribution volume [DV']. Results of a voxel based correlation analysis ( $\Delta$  5D-ASC global vs  $\Delta$ DV', threshold  $P < 0.005$ , uncorrected) using Statistical Parametric Mapping (SPM2) (Hasler, Quednow, Vollenweider, unpublished data). ### ***Comparison of hallucinogen effects and endogenous psychoses***

As noted earlier, Beringer was the first investigator to propose that hallucinogens could be used to produce a 'model psychosis' in healthy humans (Beringer, 1923). Subsequent investigations confirmed that administration of mescaline, psilocybin and LSD induces states that resemble the symptoms of the earliest phases of schizophrenia (Rinkel *et al.*, 1952, 1955; Keeler, 1965; Bowers and Freedman, 1966). Indeed, the loss of control over thought processes that occurs after ingestion of psilocybin (Vollenweider *et al.*, 1997a) closely parallels acute psychotic decompensation (Keeler, 1965; Bowers and Freedman, 1966). Despite these similarities, Hollister (1962) and other clinicians have argued that there are notable differences between the effects of hallucinogens and the symptomatology of schizophrenia, leading them to question whether hallucinogen-induced psychedelic phenomena is a valid model for endogenous psychotic states. For example, Hollister noted that auditory but not visual hallucinations are prominent in schizophrenia, whereas changes of visual perception are a characteristic effect of hallucinogens. However, disturbances in visual perception, including hallucinations and synesthesias, do occur during the acute phase of schizophrenia (McCabe *et al.*, 1972; Freedman and Chapman, 1973). Hollister (1962) also argued that schizophrenics often display social and emotional withdrawal, but this effect is rarely observed after administration of serotonergic hallucinogens. There is evidence, however, that administration of hallucinogens, especially at high doses, can sometimes induce withdrawal and states resembling catatonia (Gouzoulis-Mayfrank *et al.*, 1998a).

In a study conducted by Gouzoulis-Mayfrank and colleagues (1998b), the symptoms of schizophrenia were assessed using the APZ rating scale. The goal of that investigation was to determine, using objective criteria, whether psychotic patients experience hallucinogen-like psychedelic effects. The study compared APZ scores from 50 healthy controls and 93 patients with acute schizophrenia, schizophreniform disorder or schizoaffective disorder. The APZ scores of psychotic patients were found to be significantly higher than those of controls. The study also examined whether the APZ scores correlate with scores on the Brief Psychiatric Rating Scale (BPRS), which measures positive symptoms and general psychopathology. Correlation analysis revealed that the OB subscale of the APZ correlates with BPRS factor 3 (reflecting most of the typical positive symptoms of schizophrenia), whereas the AED subscale correlates with BPRS factor 1 (reflecting anxiety and depression). These findings confirm that patients with acute schizophrenia experience hallucinogen-like effects, indicating that the

syndrome induced by hallucinogens is a valid model of acute schizophrenia.

### **Animal models of hallucinogen effects relevant to schizophrenia**

In laboratory animals, serotonergic hallucinogens have been shown to (1) potentiate neophobia (Tilson *et al.*, 1975; Adams and Geyer, 1982, 1985); (2) increase the responsiveness to sensory stimulation (Key, 1964; Geyer *et al.*, 1978; Geyer, 1998); and (3) retard habituation in a variety of input modalities and response output systems (Key, 1964; Geyer *et al.*, 1978; Geyer, 1998; Dulawa and Geyer, 2000; Geyer and Moghaddam, 2002). Given the similarities between the psychedelic state induced by hallucinogens and the symptoms of acute schizophrenia, there has been substantial interest in developing animal models of schizophrenia based on the acute behavioral effects of hallucinogens (Geyer and Vollenweider, 2008). Unfortunately, many of the unconditioned behaviors induced by hallucinogens in animals (e.g., head-twitch response, ear scratch) have no human counterpart, and thus it is not clear how these behaviors relate to the subjective effects of hallucinogens. However, hallucinogens produce effects on habituation and prepulse inhibition (PPI) of startle in animals that are analogous to hallucinogen effects in humans. Based partially on these cross-species similarities, the effects of hallucinogens on habituation and PPI have been proposed as potential behavioral models of schizophrenia (reviewed by Powell and Geyer, 2007). A brief description of these two behavioral models is provided below.

#### ***Habituation***

Repeated presentation of irrelevant stimuli leads to a marked response decrement, a process known as habituation. Habituation is the simplest form of learning, and is necessary for selective attention. Deficits of attention and information-processing are core features of schizophrenia (Braff, 1985; Braff and Geyer, 1990). Patients with schizophrenia are often unable to filter out extraneous stimuli, leading to distractibility, sensory flooding and impaired cognition (McGhie and Chapman, 1961). Several studies have found that schizophrenic patients show deficits of startle reflex habituation, potentially contributing to the sensory overload and disorganized cognitive processes that occur in the disorder (e.g., Geyer and Braff, 1982, 1987; Bolino *et al.*, 1994; Parwani *et al.*, 2000; Ludewig *et al.*, 2003; Quednow *et al.*, 2006). An advantage of using habituation as a behavioral model is that similar

testing procedures can be used to assess habituation in experimental animals and humans. For example, LSD and mescaline have been shown to decrease habituation to startling tactile stimuli in rats (Geyer *et al.*, 1978; Braff and Geyer, 1980), similar to the finding in patients with schizophrenia.

### ***Prepulse inhibition***

The PPI paradigm has been multiply applied in order to assess the loss of sensorimotor gating functions in schizophrenia. PPI refers to the fact that weak pre-stimuli presented at brief intervals (30–500ms) prior to a startle-eliciting stimulus reduce (or gate) the amplitude of the startle response. Studies have consistently detected robust PPI deficits in schizophrenia patients (see, for example, Braff *et al.*, 1978; Braff and Geyer, 1990; Bolino *et al.*, 1994; Parwani *et al.*, 2000; Ludewig *et al.*, 2003; Quednow *et al.*, 2006). It was proposed that the mechanism underlying PPI regulates sensory input by filtering out irrelevant or distracting stimuli in order to prevent sensory information overflow and to allow for selective and efficient processing of relevant information (Swerdlow and Geyer, 1998). The consistently reported PPI deficits in schizophrenia patients contributed to the view that schizophrenia could be seen as gating- or filter-deficit disorder (Carlsson, 1995). As detailed in Chapter 4.7, hallucinogens such as LSD and DOI also disrupt PPI. Thus, the hallucinogen-treated animals tested in the PPI paradigm exhibit an increased or unfiltered responsiveness to sensory stimuli – that is, they fail to exhibit the gating or inhibition of the response normally produced by the prepulse stimulus. As reviewed elsewhere (Geyer *et al.*, 2001; Swerdlow *et al.*, 2001), this cross-species phenomenon of PPI is very robust, unlearned and ubiquitous. Indeed, depending on the testing parameters used, the hallucinogen psilocybin has been shown to produce PPI deficits in normal human volunteers (Vollenweider *et al.*, 2007). Hence, the ability of hallucinogens to alter PPI has been considered to be a useful model to study the positive symptoms of schizophrenia.

### **Serotonin receptor and transporter changes *in vivo* and *post-mortem* in schizophrenia**

Early *post-mortem* studies with schizophrenia patients revealed that 5-HT and 5-hydroxyindoleacetic acid (5-HIAA) levels were increased in subcortical brain regions such as the putamen, nucleus accumbens and globus pallidus (Crow *et al.*, 1979; Farley *et al.*, 1980), and that 5-HIAA levels are decreased in cortical regions,

including cingulate and frontal areas (Winblad *et al.*, 1979). Many subsequent studies investigated altered serotonin receptor and transporter expression in schizophrenia patients *in vivo* and *post-mortem*, especially with radio-labeled compounds. Most of these receptor investigations explored the 5-HT<sub>1A</sub> or 5-HT<sub>2A</sub> receptor density, usually with highly divergent results.

### ***5-HT<sub>1A</sub> receptors***

Among the most consistent alterations of 5-HT parameters in schizophrenia, as identified in *post-mortem* studies, is an increase in the density of 5-HT<sub>1A</sub> receptors in the PFC (Bantick *et al.*, 2001; Weinberger and Laruelle, 2002). Seven of ten studies – using either [<sup>3</sup>H]8-hydroxy-2,3-(dipropylamino)-tetralin ([<sup>3</sup>H]8-OH-DPAT) or the more specific compound [<sup>3</sup>H]WAY-100653 for 5-HT<sub>1A</sub> receptor binding and autoradiography, and/or analysis of receptor mRNA – have reported a 15–80 percent increase in 5-HT<sub>1A</sub> receptor levels in the dorsolateral or orbital PFC, whereas other brain regions such as the anterior cingulate cortex and the temporal cortex have shown less consistent results, including possible increases (for review and citations, see Bantick *et al.*, 2001; Gray *et al.*, 2006). Interestingly, the increase in prefrontal 5-HT<sub>1A</sub> receptor density was not necessarily accompanied by a change in 5-HT<sub>1A</sub> receptor mRNA (Burnet *et al.*, 1996a). Moreover, the only study that stained for 5-HT<sub>1A</sub>-like immunoreactivity did not find differences between schizophrenia patients and controls (Cruz *et al.*, 2004). Since receptors located at other cellular locations could not be visualized with the antibody used, changes in the overall density of the 5-HT<sub>1A</sub> receptor could not be excluded by this study.

In contrast to the consistent findings in *post-mortem* studies, recent investigations of 5-HT<sub>1A</sub> receptor distribution using [<sup>11</sup>C]WAY-100653 PET in schizophrenia patients are contradictory. One study reported increased binding only in the medial temporal lobe (Tauscher *et al.*, 2002), another study described decreased binding in the amygdala (Yasuno *et al.*, 2004), whereas two further studies found no alterations in cortical 5-HT<sub>1A</sub> receptor binding (Bantick *et al.*, 2004; Frankle *et al.*, 2006). Moreover, Bantick *et al.* (2004) found no differences in 5-HT<sub>1A</sub> receptor binding between clozapine-treated patients, patients medicated with antipsychotics with low 5-HT<sub>1A</sub> affinity, and healthy human volunteers. The authors concluded that clozapine did not occupy 5-HT<sub>1A</sub> receptors at clinical doses. With respect to the inconsistencies between PET and *post-mortem* studies, Frankle *et al.* (2006) suggested that the alterations found in *post-mortem* studies cannot be reliably detected in PET studies, which puts into question whether 5-HT<sub>1A</sub> receptors play a major

role in the pathophysiology of schizophrenia. Due to the fact that schizophrenia patients included in *post-mortem* studies are rarely antipsychotic-naïve, whereas PET studies have mostly assessed in drug-naïve or unmedicated patients, it is likely that the 5-HT<sub>1A</sub> receptor changes found in the majority of *post-mortem* studies are probably the result of chronic medication with antipsychotics or other psychotropics. However, in two of the *post-mortem* studies, 5-HT<sub>1A</sub> receptor increases were seen also in drug-free patients (Hashimoto *et al.*, 1991; Sumiyoshi *et al.*, 1996).

In sum, findings with respect to 5-HT<sub>1A</sub> receptor changes are highly contradictory. Whereas *post-mortem* studies consistently suggest an increase of 5-HT<sub>1A</sub> receptor especially in the PFC, PET studies did not find changes of prefrontal receptor binding. Effects of chronic antipsychotic medication may contribute to these different results. When schizophrenia patients actually display frontal up-regulation in 5-HT<sub>1A</sub> receptors, this might reflect an abnormal glutamatergic network because in the neocortex these receptors are mainly located on pyramidal cells (Bantick *et al.*, 2001).

### 5-HT<sub>2A</sub> receptors

The 5-HT<sub>2A</sub> receptor is the most intensively investigated 5-HT receptor in *post-mortem* schizophrenia studies in the last 30 years. Of 18 *post-mortem* studies, 14 reported finding decreased 5-HT<sub>2A</sub> receptor binding/densities (or decreased 5-HT<sub>2A</sub> receptor mRNA expression) in cortical areas, especially in the frontal cortex, of schizophrenia patients (for references and details, see Table 2). Two of the studies reported an increase in several brain regions, whereas the two remaining studies did not find 5-HT<sub>2A</sub> receptor changes. Moreover, only five investigations explored 5-HT<sub>2A</sub> receptors in the basal ganglia, but just one report suggested increased 5-HT<sub>2A</sub> levels, whereas the other four studies found no changes. It should be noted that the radioligands that were used in these studies have high affinity for 5-HT<sub>2A</sub> receptors, but they also label other receptor types. For example, ketanserin additionally labels  $\alpha$ -adrenoreceptors, histamine H<sub>1</sub> receptors and vesicular monoamine transporters; LSD binds to 5-HT<sub>1A</sub>, 5-HT<sub>1E</sub>, 5-HT<sub>2C</sub>, 5-HT<sub>6</sub>, 5-HT<sub>7</sub> and dopamine-D<sub>1</sub> receptors; whereas spiperone also has high affinity for D<sub>2</sub> receptors (Harrison, 1999b). This lack of specificity must be taken into account when these studies are interpreted.

Legitimately, the question has been raised whether these receptor changes are simply the result of chronic drug treatment, because most of the patients studied were treated with antipsychotics for many years. Indeed, it was shown that long-term treatment with clozapine decreases

5-HT<sub>2A</sub> receptor binding and mRNA expression in the cingulate and frontal cortex of rats. In contrast, haloperidol did not alter cortical 5-HT<sub>2A</sub> receptor density or expression in the frontal cortex of rats (Reynolds *et al.*, 1983a; Wilmot and Szczepanik, 1989; O'Dell *et al.*, 1990; Burnet *et al.*, 1996b). Other atypical antipsychotics that are 5-HT<sub>2A</sub> antagonists may also reduce cortical 5-HT<sub>2A</sub> receptors when given chronically (Mikuni and Meltzer, 1984; Andree *et al.*, 1986; Padin *et al.*, 2006). However, particularly in the early studies, only a very small number of patients were treated with clozapine or other atypical substances. Additionally, antipsychotic medication may increase rather than decrease 5-HT<sub>2A</sub> receptor expression (Hernandez and Sokolov, 2000), and many studies also found decreased 5-HT<sub>2A</sub> receptor densities in unmedicated subjects, or did not detect dose effects of previous antipsychotic drug treatment (Table 2). Thus, the decrease of 5-HT<sub>2A</sub> receptors especially in the dorsolateral PFC could not be explained only by chronic drug treatment; a pathological process also has to be involved (Dean, 2003).

PET studies applying 5-HT<sub>2A</sub> receptor tracers to schizophrenia patients show controversial results. Three studies using [<sup>18</sup>F]sepiroperone and one study using [<sup>11</sup>C]*N*-methylspiperone did not show any significant differences in 5-HT<sub>2A</sub> receptor densities between schizophrenia patients and controls, either with regions-of-interest (ROI)-based or voxel-based analyses (Trichard *et al.*, 1998; Lewis *et al.*, 1999; Okubo *et al.*, 2000; Verhoeff *et al.*, 2000). However, both tracers suffer from a relatively low affinity for 5-HT<sub>2A</sub> receptors, and thus they have an insufficient signal-to-noise ratio in subcortical areas (Erritzoe *et al.*, 2008). In contrast, one study using [<sup>18</sup>F]sepiroperone found decreased frontal 5-HT<sub>2A</sub> receptor densities in antipsychotic-naïve schizophrenia patients (−16.3 percent; Ngan *et al.*, 2000), while a recently published study using the more selective 5-HT<sub>2A</sub> antagonist [<sup>18</sup>F]altanserin could not demonstrate a frontal decrease but rather an increase of 5-HT<sub>2A</sub> receptors in the caudate in a similar patient sample (Erritzoe *et al.*, 2008). Two further studies investigated 5-HT<sub>2A</sub> receptor density with [<sup>18</sup>F]altanserin PET in subjects supposed to be in a prodromal state of schizophrenia and both reported decreased binding of the radio tracer in the PFC (Hurlemann *et al.*, 2005, 2008). In the later study, Hurlemann *et al.* (2008) additionally detected decreased 5-HT<sub>2A</sub> receptor binding in the right insular cortex, the left amygdala, both hippocampi, the right caudate and the left putamen in never-medicated subjects in a late prodromal stage. Interestingly, a low 5-HT<sub>2A</sub> receptor density in the right caudate predicted later conversion to full-blown psychosis, a finding that is highly discrepant with the results of Erritzoe *et al.* (2008). Taken together, in contrast to the consistency of the *post-mortem* findings,

**Table 2** *Post-mortem studies investigating 5-HT<sub>2A</sub> receptor density in schizophrenia (modified and updated according to Harrison, 1999a)*

Study	Method <sup>1</sup>	Brain region <sup>2</sup>	Cases/controls	Medicated cases	Main findings
<b>Decrease in cortical binding</b>					
Bennett <i>et al.</i> (1979)	HB with [ <sup>3</sup> H]LSD	BA 6, 8–11, 44–47	26/25 <sup>3</sup>	18	↓ 40–50%, no effect of medication
Mita <i>et al.</i> (1986)	HB with [ <sup>3</sup> H]ketanserin	BA 9	11/9	7	↓ 36%, no effect of medication
Arora and Meltzer (1991)	HB with [ <sup>3</sup> H]spiperone	BA 8/9	11/11	11	↓ 33%, no effect of medication
Laruelle <i>et al.</i> (1993a)	HB with [ <sup>3</sup> H]ketanserin	BA 10, 17/18	10/12 <sup>4</sup>	6	↓ 21% in BA 10, no effect of medication
Burnet <i>et al.</i> (1993b)	a) RA with [ <sup>3</sup> H]ketanserin	BA 17, 22, 46, MTL, AC	13/15	12	↓ 27% in BA 46, ↓ 38% MTL, similar trend in AC
	b) mRNA using ISH				↓ 49–63% in BA 17, 22, 46, AC, ↔ in MTL
Dean and Hayes (1996)	RA with [ <sup>3</sup> H]ketanserin	BA 8, 9, 10	20/20	19	↓ 25–33% in all frontal regions
Gurevich and Joyce (1997)	RA with [ <sup>125</sup> I]LSD	BA 1–3, 4, 6, 8, 9, 31, 32, 40, 44–46, AC, PC	10/12	5	↓ ~60% in BA 6, 24 in drug-free cases, ↓ ~70–90% in all brain regions in medicated cases
Kouzmenko <i>et al.</i> (1997)	RA with [ <sup>3</sup> H]ketanserin	BA 9/46	63/62 <sup>5</sup>	60	↓ 33%
Dean <i>et al.</i> (1998)	RA with [ <sup>3</sup> H]ketanserin	BA 9	55/55	55	↓ 33%
Dean <i>et al.</i> (1999a)	RA with [ <sup>3</sup> H]ketanserin	BA 9	19/19	17	↓ 35%
Hernandez and Sokolov (2000)	mRNA using ISH	BA 9	21/14	18	↓ 60% in patients being drug free for > 26 weeks, antipsychotic treatment increased 5-HT <sub>2A</sub> mRNA
Pralong <i>et al.</i> (2000)	a) RA with [ <sup>3</sup> H]ketanserin	BA 22 (planum temporale)	20/20	17	↓ 32%
	b) HB with [ <sup>3</sup> H]ketanserin	BA 22 (planum temporale)	10/10	10	↓ 34% B <sub>max</sub> , ↑ 119%, changes in affinity (K <sub>d</sub> ) but not density (B <sub>max</sub> ) explained by medication effects
Scarr <i>et al.</i> (2004)	RA with [ <sup>3</sup> H]ketanserin	MTL (only hippocampus)	20/20	20	↓ ~29–47% across different regions of hippocampus
Matsumoto <i>et al.</i> (2005)	RA with [ <sup>3</sup> H]ketanserin	BA 9, MTL	6/6	6	↓ 39% in BA 9, ↔ in MTL
<b>Increase in cortical binding</b>					
Whitaker <i>et al.</i> (1981)	HB with [ <sup>3</sup> H]LSD	BA 4, 10, 11	13/8	8	↔, ↑ 55% in unmedicated cases
Joyce <i>et al.</i> (1993)	RA with [ <sup>125</sup> I]LSD	BA 4, 9, 21, AC, PC, MTL	8/10	4	↑ ~50–100% only in MTL, BA 21, PC
<b>No changes in cortical binding</b>					
Reynolds <i>et al.</i> (1983b)	HB with [ <sup>3</sup> H]ketanserin	BA 10	11/10	11	↔

(Continued)

**Table 2** (Continued)

Study	Method <sup>1</sup>	Brain region <sup>2</sup>	Cases/controls	Medicated cases	Main findings
Dean <i>et al.</i> (1996)	HB with [ <sup>3</sup> H]ketanserin	BA 9	20/20	19	↔
<b>Increase in basal ganglia</b>					
Joyce <i>et al.</i> (1993)	RA with [ <sup>3</sup> H]ketanserin	Caudate, putamen, NAC	8/10	4	↑ ~30–75%
<b>No changes in basal ganglia</b>					
Mackay <i>et al.</i> (1978)	HB with [ <sup>3</sup> H]spiperone	NAC	26/17	?	↔
Owen <i>et al.</i> (1981)	HB with [ <sup>3</sup> H]LSD, [ <sup>3</sup> H]5-HT	Caudate, putamen	19/20	?12	↔
Seeman <i>et al.</i> (1993)	HB with [ <sup>3</sup> H]ketanserin	Striatum	9/4	6	↔
Matsumoto <i>et al.</i> (2005)	RA with [ <sup>3</sup> H]ketanserin	Caudate, putamen	6/6	6	Not significant but strong trend for decrease (↓ 34%)

Notes:

<sup>1</sup> HB, homogenate binding; ISH, *in situ* hybridization; RA, receptor autoradiography.<sup>2</sup> BA, Brodmann area; BA 4, motor cortex; BA 6, 8, 9, 10, 11, 44–47, prefrontal cortex; BA 17/18, occipital cortex; BA 21, 22, temporal cortex; AC, anterior cingulate cortex; PC, posterior cingulate cortex; MTL, mediotemporal lobe including hippocampus, amygdala, uncus, parahippocampal gyrus, entorhinal cortex; NAC, nucleus accumbens.<sup>3</sup> Sum of three separate case–control groups. The decrease in [<sup>3</sup>H]LSD binding was demonstrated in all three comparisons.<sup>4</sup> Includes six subjects with schizoaffective disorder. Significant differences remained when these subjects were excluded.<sup>5</sup> Included cases of Burnet *et al.* (1996b) and Dean and Hayes (1996).

the PET results are highly contradictory. Given that the methodological differences between the PET studies are not really obvious, further studies are needed to clarify whether 5-HT<sub>2A</sub> receptor changes could also be detected with an *in vivo* imaging approach. The new and highly selective 5-HT<sub>2A</sub> receptor radioligand [<sup>11</sup>C]MDL 100,907 may be a promising tool to further investigate 5-HT<sub>2A</sub> receptor alterations in schizophrenia (Ito *et al.*, 1998).

### Other serotonin receptors

Other serotonin receptor types have been investigated in *post-mortem* studies: two studies using [<sup>3</sup>H]GR113808 autoradiography showed that the density of 5-HT<sub>4</sub> receptors is unaltered in either the dorsolateral PFC or the hippocampus of deceased schizophrenia patients when compared to control subjects (Dean *et al.*, 1999b; Scarr *et al.*, 2004). A *post-mortem* study investigating the concentration of 5-HT<sub>3</sub> receptors (which is the only ion channel in the 5-HT receptor family) in the amygdala of schizophrenia patients and controls with [<sup>3</sup>H]LY278584 autoradiography did not find group differences (Abi-Dargham *et al.*, 1993). The 5-HT<sub>6</sub> receptor density measured with [<sup>125</sup>I]SB-258585 in the frontal cortex was not changed in 20 schizophrenia patients compared to 17 control subjects (East *et al.*, 2002). Recently, two studies

investigated the densities of 5-HT<sub>1D</sub> and 5-HT<sub>1F</sub> receptors in the dorsolateral PFC and the hippocampus, respectively, of schizophrenia patients using methiothepin-sensitive and -insensitive [<sup>3</sup>H]sumatriptane autoradiography (Scarr *et al.*, 2004; Dean *et al.*, 2006). While Scarr *et al.* (2004) reported a decrease of 5-HT<sub>1F</sub> but unaltered 5-HT<sub>1D</sub> receptors in the hippocampus, Dean and colleagues did not find any changes in HT<sub>1F</sub> and 5-HT<sub>1D</sub> receptors in the dorsolateral PFC of the patients. In the same study, however, Dean *et al.* (2006) found decreased 5-HT<sub>7</sub> receptor levels in dorsolateral PFC of schizophrenia patients using [<sup>3</sup>H]SB-269970. By contrast, haloperidol treatment increased the number of 5-HT<sub>7</sub> receptors in the cortex of rats (Dean *et al.*, 2006). The authors therefore concluded that 5-HT<sub>7</sub> receptors are possibly involved in the pathological processes of schizophrenia and that appropriate 5-HT<sub>7</sub> receptor levels may be critical for normal cortical development. These recent findings regarding alterations of HT<sub>1F</sub> and 5-HT<sub>7</sub> receptors in schizophrenia need confirmation by further *post-mortem* and, if possible, PET studies.

### Serotonin transporter (SERT)

Serotonin transporters (SERT) are located presynaptically on serotonergic axon terminals and are believed

to serve as an index of serotonergic innervation (Abi-Dargham and Krystal, 2000). Two *post-mortem* studies applying [ $^3\text{H}$ ]cyano-imipramine and [ $^3\text{H}$ ]paroxetine initially showed that the density of SERT was decreased in the frontal cortex (Joyce *et al.*, 1993; Laruelle *et al.*, 1993a). In the study of Joyce and colleagues (1993), SERT was also decreased in the anterior and posterior cingulate cortex of schizophrenia patients, but increased in the striatum. On the contrary, later studies using radio-labeled serotonin reuptake inhibitors (SRIs), such as [ $^3\text{H}$ ]paroxetine, [ $^3\text{H}$ ]citalopram or [ $^{125}\text{I}$ ]RTI-55, did not demonstrate any alterations in the SERT density in several brain regions, including the PFC or the cingulate cortex, in schizophrenia patients (Dean *et al.*, 1995, 1999b; Naylor *et al.*, 1996; Gurevich and Joyce, 1997). In fact, three of these studies did not report altered SERT densities but did find a decrease in the affinity of [ $^3\text{H}$ ]paroxetine for SERT in hippocampal membranes, whereas the affinity of [ $^3\text{H}$ ]paroxetine for SERT binding in the frontal cortex was unaltered (Dean *et al.*, 1995, 1996; Naylor *et al.*, 1996). Gurevich and Joyce (1997) concluded that the initial positive findings were probably confounded by the large number of schizophrenia patients in the samples who committed suicide. The same may be true for the finding of decreased SRI affinity in hippocampal SERT, as Dean and colleagues showed that the effect was more pronounced in schizophrenia patients who committed suicide (Dean *et al.*, 2006).

Examining the expression of SERT mRNA, Hernandez and Sokolov (1997) found a four-fold increase in the level of SERT mRNA in the dorsolateral PFC, but a two-fold decrease in the temporolateral cortex, of schizophrenics. However, since these changes were strongly correlated with previous antipsychotic drug treatment, they cannot be attributed to the illness process.

A SPECT study using [ $^{123}\text{I}$ ]RTI-55 could not detect any differences in SERT concentration in midbrain areas of schizophrenia patients (Laruelle *et al.*, 2000). However, [ $^{123}\text{I}$ ]RTI-55 is not specific for SERT but also labels the dopamine transporter (DAT) (Neumeyer *et al.*, 1991). In addition, [ $^{123}\text{I}$ ]RTI-55 does not permit measurement of SERT availability in regions other than the midbrain (Laruelle *et al.*, 1993b). Recently, Frankle *et al.* (2005) also failed to detect any differences in SERT binding between schizophrenia patients and controls when using the more specific radiotracer [ $^{11}\text{C}$ ]DASB. However, [ $^{11}\text{C}$ ]DASB does not have a good signal-to-noise ratio when assessing regions with low SERT density such as the neocortex (Frankle *et al.*, 2005), complicating a possible detection of group differences in, for example, the frontal cortex. Thus, taking all these findings into account, it is unlikely that SERT plays an important role in the pathophysiology of schizophrenia.

## Genetic association studies regarding schizophrenia and serotonin

Given that, to date, more than 1400 association studies searching for potential genetic risk factors have been published with largely inconsistent results, a regularly updated online database ('SzGene') including meta-analyses of all published genetic studies for schizophrenia has recently been established (Allen *et al.*, 2008; [www.schizophreniaforum.org](http://www.schizophreniaforum.org)). Single nucleotide polymorphisms (SNPs) having genotype data available in at least four independent case-control samples were included in random-effect meta-analyses using allelic contrasts. In the ranking of the meta-analyses showing the strongest effect sizes, two serotonin-related SNPs are currently placed in the top 20 (status 30 September, 2009): the tryptophan hydroxylase 1 (TPH1) A218C polymorphism ranked eleventh (odds ratio (OR) = 1.25), and the 5-HT<sub>2A</sub> A-1438G polymorphism ranked sixteenth (OR = 1.16). Table 3 displays all serotonin SNPs for which meta-analyses were done. For comparison, the strongest effect so far was shown for the A2897G polymorphism of the disrupted-in-schizophrenia gene 1 (DISC1; OR = 1.80, confidence interval (CI) = 1.2–2.68). The second ranking belongs to the A277C polymorphism of the vesicular monoamine transporter 1 (VMAT1; OR = 1.63, CI = 1.03–2.57). VMAT1 is involved in the intracellular transport of all monoamines including serotonin. The rs6556547 SNP of the GABA-A beta-2 receptor (OR = 0.70, CI = 0.52–0.95), is ranked third. These ORs reported for schizophrenia susceptibility genes are comparable with those found in other genetically complex neuropsychiatric diseases such as Alzheimer's disease (Allen *et al.*, 2008).

TPH1 and TPH2 are rate-limiting enzymes in 5-HT synthesis, but while TPH1 is primarily expressed in peripheral regions such as the pineal gland and enterochromaffin cells of the gut, TPH2 is expressed predominantly in serotonergic neurons of the raphe nuclei (Zhang *et al.*, 2006). Moreover, the TPH1 A779C and A218C SNPs are intronic (non-coding), and alternative mechanisms probably providing gene expression from intronic sequences such as splicing and exon skipping have been ruled out (Shaltiel *et al.*, 2005). For these reasons, the positive associations between the TPH1 A218C polymorphism and schizophrenia were strongly criticized (Reuter *et al.*, 2007). However, in a *post-mortem* study, Zill *et al.* (2007) recently demonstrated the expression of TPH1 mRNA in several brain regions. Therefore, it seems to be largely unclear to date which role TPH1 plays in cerebral function and schizophrenia. Most likely, the intronic TPH1 A218C SNP is in linkage disequilibrium with other functional as yet unidentified gene variations. Variations of the TPH2 gene have not been positively linked to

**Table 3** Meta-analyses of association studies between polymorphisms of the serotonin system and schizophrenia\*

Gene	Substrate	SNP	Chromosome (location)	Synonymy	Number of studies	Number of patients	Number of controls	Minor allele (%) frequency in controls)	Risk allele	Odds ratio (all studies)	95% confidence interval
5-HT <sub>1B</sub>	Receptor	rs6296 (G861C)	6 (6q13)	Synonymous	4	763	1123	C (38%)	C	0.95	0.75–1.20

Published on the SchizophreniaGene database ([www.schizophreniaforum.org/res/sczgene/default.asp](http://www.schizophreniaforum.org/res/sczgene/default.asp), status 30 September 2009).

Meta-analyses were done for SNPs with a minor allele frequency > 1%, and when more than three independent case–control samples were available (Allen *et al.*, 2008).

Abbreviations: SNP, single nucleotide polymorphisms; SERT, serotonin transporter; TPH1, tryptophan hydroxylase 1.

schizophrenia so far (De Luca *et al.*, 2005; Higashi *et al.*, 2007).

The positive association findings regarding the 5-HT<sub>2A</sub> A-1438G polymorphism once more underscore the significance of this receptor for schizophrenia (Table 3). The A-1438G polymorphism is silent and does not result in an alteration of the amino acid sequence of the 5-HT<sub>2A</sub> receptor, but is located within the promoter region of the 5-HT<sub>2A</sub> receptor gene (Spurlock *et al.*, 1998), and thus it has been proposed that the A-1438G polymorphism alters promoter activity and expression of 5-HT<sub>2A</sub> receptors (Parsons *et al.*, 2004). The 5-HT<sub>2A</sub> A-1438G and T102G receptor polymorphisms are usually in perfect linkage disequilibrium. We have recently shown that the sensorimotor gating deficits of schizophrenia patients – which are seen as a promising endophenotype of schizophrenia (Gottesman and Gould, 2003) – are strongly modulated by the 5-HT<sub>2A</sub> A-1438G and T102C receptor SNPs that were completely linked in our sample (Quednow *et al.*, 2008). In accordance with the genetic association studies, carriers of the high-risk G and C alleles displayed diminished sensorimotor gating. We have just replicated this finding in a sample of 94 normal subjects (Quednow *et al.*, 2009). In conclusion, the C allele of the T102C variation and

the G allele of the A-1438G variation may cause lower 5-HT<sub>2A</sub> receptor densities in some brain areas, which may lead to a less flexible serotonin system and worse dopaminergic modulation (Serretti *et al.*, 2007).

The SzGene meta-analyses regarding 5-HT<sub>1B</sub> G861C, 5-HT<sub>2A</sub> His452Tyr and 5-HT<sub>6</sub> C267T receptor SNPs, and the well-known SERT polymorphisms, suggest rather weak or no associations with schizophrenia (Table 3).

Currently, there are also some new interesting data coming from single association studies that still have to be replicated. Huang *et al.* (2004) reported an increased frequency of the G allele of the 5-HT<sub>1A</sub> C-1019G promoter polymorphism in schizophrenia patients. The occurrence of the G allele is associated with enhanced gene expression (Lemondé *et al.*, 2003), which would fit with the *post-mortem* data on increased 5-HT<sub>1A</sub> receptor levels in the PFC of schizophrenics. However, in a large *post-mortem* autoradiographic study, Huang *et al.* (2004) could not demonstrate differences in 5-HT<sub>1A</sub> receptor binding between 5-HT<sub>1A</sub> C-1019G genotypes in suicidal, depressed and healthy subjects. Moreover, significant associations were reported for the 5-HT<sub>2C</sub> G68C (Segman *et al.*, 2000), a 5-HT<sub>4</sub> haplotype (Suzuki *et al.*, 2003), and several 5-HT<sub>5A</sub> (Birkett *et al.*, 2000; Iwata *et al.*, 2001;

Dubertret *et al.*, 2004) and two 5-HT<sub>7</sub> receptor polymorphisms (Ikeda *et al.*, 2006). There have also, however, been some negative reports for 5-HT<sub>2C</sub> G68C (Segman *et al.*, 1997; Semwal *et al.*, 2002) and the 5-HT<sub>7</sub> receptor polymorphisms (Fallin *et al.*, 2005). Further studies are needed to finally assess the sustainability of these initial findings.

Not only schizophrenia itself, but also drug response or risk for developing side effects such as tardive dyskinesia or weight gain, were the subject of pharmacogenetic studies of mutations in the serotonin system (for a comprehensive review, see Arranz and de Leon, 2007). The aim of these studies was the development of genetic predictors for treatment response and side effects to preselect and therefore improve antipsychotic treatment. The functional C-1019G variant of the 5-HT<sub>1A</sub> receptor was recently demonstrated to influence the response to atypical antipsychotics (Reynolds *et al.*, 2006; Wang *et al.*, 2008; Mossner *et al.*, 2009). These studies have consistently shown that carriers of the C allele show greater improvement, especially in regard to negative symptoms. A number of studies reported significant associations between the linked 5-HT<sub>2A</sub> A-1438G and T102C receptor SNPs and response to atypical antipsychotics (mostly clozapine), but there are some discrepant results with respect to the risk alleles for non-responding (Arranz *et al.*, 1995, 1998a, 1998b; Joobert *et al.*, 1999; Yu *et al.*, 2001; Lane *et al.*, 2002; Hamdani *et al.*, 2005; see also Arranz and de Leon, 2007). In addition, there are several studies reporting that there is no association between the T102C substitution and the therapeutic response to clozapine and other antipsychotics (Masellis *et al.*, 1995; Nothen *et al.*, 1995; Jonsson *et al.*, 1996; Malhotra *et al.*, 1996; Lin *et al.*, 1999). A more consistent picture comes from studies showing an influence of the functional His452Tyr polymorphism of the 5-HT<sub>2A</sub> receptor on the clozapine response (Arranz *et al.*, 1996; Masellis *et al.*, 1998). Although several other studies failed to detect an association of this SNP and treatment response (Masellis *et al.*, 1995; Nothen *et al.*, 1995; Jonsson *et al.*, 1996; Malhotra *et al.*, 1996; Lin *et al.*, 1999), a recent meta-analysis has shown a relatively strong association of the Tyr variant with poor response to clozapine (Arranz *et al.*, 1998b). Mutations in the promoter (VNTR, T-759C and G-995A) and coding region (Cys23Ser) of the 5-HT<sub>2C</sub> receptor have also been associated with clozapine response and improvement in negative symptoms (Sodhi *et al.*, 1995; Arranz *et al.*, 2000a; Reynolds *et al.*, 2005). A further study was unable to detect an effect of the Cys23Ser SNP on treatment response (Rietschel *et al.*, 1997). In sum, the contribution of the variants to general drug response is relatively moderate, possibly indicating contribution to specific symptoms or side effects that need

further investigation (Arranz and de Leon, 2007). There are also some indices for an association of the 5-HT<sub>6</sub> T-267C receptor variant with the response to treatment with clozapine and risperidone in Chinese patients (Yu *et al.*, 1999; Lane *et al.*, 2004), although this association has not been replicated in US patients (Masellis *et al.*, 2001).

Additionally, SERT polymorphisms have been investigated in respect to drug response but, with the exception of an initial positive finding (Arranz *et al.*, 2000b), all further reports did not find significant associations (Arranz *et al.*, 2000a; Tsai *et al.*, 2000; Kaiser *et al.*, 2001). Through combining the data of gene variants previously associated with clozapine response, Arranz *et al.* (2000b) found that a combination of SNPs in the genes coding for 5-HT<sub>2A</sub>, 5-HT<sub>2C</sub>, histamine H<sub>2</sub> receptors and the SERT resulted in the correct prediction of response in 76 percent of cases. However, so far this finding has not been replicated (Schumacher *et al.*, 2000).

The findings with respect to the association of 5-HT<sub>2A</sub> polymorphisms and tardive dyskinesia are controversial (Basile *et al.*, 2001; Segman *et al.*, 2001; Tan *et al.*, 2001; Lattuada *et al.*, 2004; Deshpande *et al.*, 2005; Lerer *et al.*, 2005). The same is true for 5-HT<sub>2C</sub> polymorphisms (Rietschel *et al.*, 1997; Zhang *et al.*, 2002; Deshpande *et al.*, 2005). Two recent studies reported promising results regarding a possible interaction of the 5-HT<sub>2A</sub>, 5-HT<sub>2C</sub> and D<sub>3</sub> receptor genotype with respect to the risk of developing tardive dyskinesia under antipsychotic treatment (Segman *et al.*, 2000; Segman and Lerer, 2002).

The most significant results associated the 5-HT<sub>2C</sub> T-759C receptor variant with antipsychotic-induced weight gain (Arranz and de Leon, 2007). Although a number of studies failed to replicate this finding (Hong *et al.*, 2001; Basile *et al.*, 2002; Tsai *et al.*, 2002; Theisen *et al.*, 2004), the evidence for a protective effect of the T allele is convincing (Reynolds *et al.*, 2002b, 2003; Buckland *et al.*, 2005; Ellingrod *et al.*, 2005; Miller *et al.*, 2005; Templeman *et al.*, 2005). Given the strength of the reported associations, this could be a discovery with a useful clinical application as a predictor of drug-induced weight gain (Arranz and de Leon, 2007).

In summary, genetic studies imply a critical role of mainly 5-HT<sub>1A</sub> and 5-HT<sub>2A</sub> receptors in the pathophysiology of schizophrenia and drug-response to antipsychotics.

## Serotonergic mechanisms of atypical antipsychotics

### 5-HT<sub>2A</sub> receptor antagonism

For a long time, one of the most important arguments for an involvement of the serotonin system in the etiology of schizophrenia was the serotonergic action of most

of the so-called atypical antipsychotics. Due to clinical experiences with the early antipsychotics, neuropharmacologists initially believed that extrapyramidal side effects (EPS) are an essential part of the antipsychotic effectiveness. The antiquated term 'neuroleptics' ('seize the neuron') still refers to this association (Lidow, 2000). The reason for the positive correlation of antipsychotic effectiveness and EPS is that the antipsychotic potency of the early neuroleptics is proportional to their ability to block striatal  $D_2$  receptors, which is also the cause for EPS (Seeman *et al.*, 1976). As a consequence,  $D_2$  receptor blockade was proposed to be the principal mechanism of action of neuroleptics known until then (Creese *et al.*, 1976), such as the phenothiazines chlorpromazine, perphenazine, fluphenazine and thioridazine, the thioxanthenes thiothixene and flupentixol, and the butyrophenone haloperidol (which is still the most widely used neuroleptic drug). However, the dibenzodiazepine clozapine broke these rules, because its therapeutic effectiveness was not paired with notable EPS. Therefore, clozapine was described as an 'atypical' antipsychotic.<sup>2</sup> Unfortunately, the conditions for atypicality are not well defined. The narrowest definition is that atypical drugs produce lower EPS than typical drugs. However, in the past two decades several further prerequisites have been proposed – that atypical drugs should have (1) a lower capacity to elevate prolactin levels and more strongly ameliorate negative and cognitive symptoms of schizophrenia compared to typical substances; (2) a multi-receptor profile, and higher *in vivo* selectivity for corticolimbic  $D_2$  receptors compared to striatal  $D_2$  receptors; and (3) a higher  $D_4$  receptor affinity, and a serotonergic component or a higher affinity for 5-HT<sub>2A</sub> receptors than for  $D_2$  receptors (Meltzer, 1991, 1999; Blin, 1999; Lidow, 2000; Seeman, 2002). It becomes clear that, in the end, all these definitions are derived from the multiple mechanisms of action of clozapine, and thus only clozapine itself matches all of these criteria, reducing the concept of atypicality to absurdity.

Although clozapine is still the gold standard regarding antipsychotic effectiveness, it has a not especially rare (0.5–2 percent) and potentially life-threatening side effect: agranulocytosis (Buchanan, 1995). Therefore, scientists have aimed to develop novel antipsychotics having the antipsychotic potency but not the dangerous side effects of clozapine. Given that the superior efficacy of clozapine had been attributed to its high 5-HT<sub>2A</sub> receptor selectivity relative to the  $D_2$  receptor (Meltzer *et al.*, 1989; Meltzer,

1991), the development of 'balanced' 5-HT<sub>2A</sub>/ $D_2$  antagonists as potential antipsychotics was initiated in the late 1980s (Abi-Dargham and Krystal, 2000). This approach led to the discovery of novel antipsychotic substances, such as risperidone, olanzapine, quetiapine, ziprasidone and sertindole. All these compounds have higher affinity for the 5-HT<sub>2A</sub> receptor than for the  $D_2$  receptor, even if none of them shows as high a  $D_2$ /5-HT<sub>2A</sub>-binding ratio as clozapine (only the dibenzoxazepine amoxapine has a higher ratio than clozapine) (Seeman, 2002). As a consequence, Meltzer (1999) proposed that atypical antipsychotics with a high  $D_2$ /5-HT<sub>2A</sub>-binding ratio are more effective against negative symptoms, show a stronger improvement of cognitive functions, and cause less EPS than typical antipsychotics. Several clinical trials have shown that atypical antipsychotics with strong 5-HT<sub>2A</sub> antagonism – first and foremost clozapine – improve negative symptoms more efficaciously than typical compounds (see, for example, Kane *et al.*, 1988; Marder and Meibach, 1994; Moller *et al.*, 1995; Tollefson and Sanger, 1997). However, meta-analyses revealed rather moderate advantages of atypical antipsychotics in the treatment of negative symptoms (Carman *et al.*, 1995; Leucht *et al.*, 1999, 2009). Some scientists argued that these beneficial effects are only related to the improvement of secondary negative symptoms, which are correlated with the improvement of positive symptoms, depressive symptoms, EPS or environmental deprivation, but that primary negative symptoms (also called as the 'deficit syndrome') are still unaffected by atypicals (Carpenter *et al.*, 1995; Buchanan *et al.*, 1998; Lidow, 2000). Moreover, the view that a 5-HT<sub>2A</sub> receptor blockade is probably not necessary to improve negative symptoms is supported by large meta-analyses showing that amisulpride – an atypical antipsychotic that is a selective  $D_2$ / $D_3$  receptor antagonist – has a comparable efficacy to clozapine with regard to negative symptoms (Leucht *et al.*, 2002, 2009).

Cognitive dysfunctions constitute core symptoms of schizophrenia, and improvement of cognitive function is highly relevant for functional outcome such as social and occupational functioning (Green, 1996; Liddle, 2000). Many studies have shown that when compared to haloperidol, the atypicals clozapine, risperidone and olanzapine differently improved functioning in several cognitive domains, including semantic memory, verbal learning and memory, sustained attention, and working memory (Kern *et al.*, 1999; Meltzer and McGurk, 1999; Purdon *et al.*, 2000; Bilder *et al.*, 2002). However, most of these clinical trials did not use a control group or did not measure the control groups repeatedly. Meanwhile, recent data suggest that the measured cognitive improvements are only in the range of the expected test–retest enhancement (Goldberg *et al.*, 2007; Quednow and Wagner, unpublished data).

<sup>2</sup> Second- or new-generation antipsychotics, multireceptor antipsychotics, or modern antipsychotics are often used (but not necessarily better) synonyms for atypical antipsychotics. Typical antipsychotics are also termed as classical or first-generation antipsychotics or neuroleptics, respectively.

Additionally, the large ( $n = 817$ ) CATIE (Clinical Antipsychotic Trials of Intervention Effectiveness) schizophrenia trial funded by the National Institute of Mental Health (NIMH) has recently shown only small effects of several atypical drugs on neurocognitive composite scores after 2, 6 and 18 months of continued treatment (Keefe *et al.*, 2007). After 2 months, treatment with the atypicals ziprasidone ( $z = 0.12$ ), olanzapine (0.13), quetiapine (0.18) and risperidone (0.26), as well as the typical antipsychotic perphenazine (0.25) (where  $z$  is the least-squares mean improvement in the neurocognitive composite score), resulted in only small but significant neurocognitive improvements, with no significant differences between treatment groups. In contrast, after 18 months of treatment, neurocognitive enhancement was significantly greater in the perphenazine group than in the olanzapine and risperidone groups, despite the fact that perphenazine is a stronger  $D_2$  receptor than a  $5-HT_{2A}$  receptor blocker. This is in line with our previous data that treatment with the selective  $D_2/D_3$  blocker amisulpride resulted in greater improvement of all cognitive domains (attention, executive function, working memory and declarative memory) in schizophrenia patients compared to the clozapine-copy olanzapine (Wagner *et al.*, 2005). These data strongly call the following two hypotheses into question: (1) that atypical antipsychotics improve cognitive deficits beyond simple test-retest effects; and (2) that  $5-HT_{2A}$  receptor blockade is necessary for the cognition enhancing effects of atypical substances.

A recent meta-analysis showed that clozapine is still the antipsychotic drug with the lowest risk to produce EPS (measured by the amount of antiparkinsonian medication), followed by sertindole and olanzapine (Leucht *et al.*, 2009). Several suggestions have been made to explain the low probability of EPS under clozapine treatment. The anticholinergic properties, the lack of ability to increase acetylcholine in the striatum,  $D_1$  and  $D_4$  receptor blockade,  $\alpha_1$ - or  $\alpha_2$ -adrenoreceptor antagonism, and the  $5-HT_{2A}$  receptor antagonism of clozapine have been proposed to reduce the risk of EPS. Data from animal models of schizophrenia as well as clinical data suggest that a high  $5-HT_{2A}$  receptor blockade in combination with a low  $D_2$  receptor blockade may help to avoid EPS, whereas the  $D_1$  receptor did not play a meaningful role (Meltzer, 1999; Roth and Meltzer, 2000). Given that many atypical compounds still induce EPS if higher doses are given,  $5-HT_{2A}$  blockade may not be sufficient for the reduction of EPS in the presence of complete or near-complete  $D_2$  blockade. However,  $5-HT_{2A}$  antagonism may reduce the risk for EPS when  $D_2$  receptors are not completely saturated (Abi-Dargham and Krystal, 2000).

Animal studies first indicated that selective  $5-HT_{2A}$  receptor antagonists lacking a dopaminergic component

may have antipsychotic properties (Geyer *et al.*, 2001). The selective  $5-HT_{2A}$  receptor blocker MDL 100,907 was the first compound whose antipsychotic activity was exclusively predicted by preclinical animal models (Varty *et al.*, 1999). In a subsequent clinical trial MDL 100,907 was not sufficiently more effective than haloperidol in the treatment of schizophrenia, although it was more effective than placebo in reducing psychotic symptoms (de Paulis, 2001). Nevertheless, so far there is no efficacious and approved antipsychotic without a dopaminergic mechanism of action. Moreover, the mechanism underlying the therapeutic superiority of clozapine is still unclear. One alternative hypothesis for atypicality focused on the special kinetics of interaction with the  $D_2$  receptor displayed by atypical drugs and, therefore, negating the role of  $5-HT_{2A}$  receptors (Kapur and Seeman, 2001). Data reported in Seeman (2002) are interpreted to suggest that most of the atypical drugs dissociate much faster from  $D_2$  receptors than do typical compounds. The dibenzapines clozapine and quetiapine and the benzamides amisulpride and remoxipride show the fastest dissociation from the  $D_2$  receptor. Seeman (2002) concluded that transient occupation of  $D_2$  receptors allows relatively normal dopamine neurotransmission, which is likely to be a prerequisite for normal prolactin levels, intact cognition and avoidance of EPS. This 'fast-off- $D_2$ ' theory was strongly criticized because it applies only to clozapine and quetiapine and is inconsistent with the relatively slow dissociation of several atypicals, including olanzapine, risperidone, ziprasidone and sertindole (Meltzer *et al.*, 2003). However, so far there is no other theory that explains the high antipsychotic efficacy of both clozapine and amisulpride.

Schizophrenia is most likely not a homogeneous entity of an illness, but rather a cluster of diverse schizophreniform diseases with different pathogeneses. Thus, some patients may have more benefit from a serotonergic compound than others. However, to date there are no criteria to safely predict the response to treatment with either antipsychotic.

### Role of other 5-HT receptors

Most of the atypical antipsychotics have affinities for multiple 5-HT receptors (Table 4). This section briefly discusses the interaction of antipsychotics with  $5-HT_{1A}$ ,  $5-HT_{2C}$ ,  $5-HT_3$ ,  $5-HT_4$ ,  $5-HT_6$  and  $5-HT_7$  receptors.

Numerous antipsychotics display activity at human  $5-HT_{1A}$  receptors – aripiprazole, clozapine, quetiapine and ziprasidone display marked affinity and act as agonists or partial agonists, whereas risperidone and sertindole display low affinity and act as antagonists. Moreover, several of the typical compounds, including

haloperidol and chlorpromazine, also exhibit relatively low affinity and antagonistic properties at 5-HT<sub>1A</sub> receptors (Newman-Tancredi *et al.*, 1998; Shapiro *et al.*, 2003). Thus, a specific 5-HT<sub>1A</sub> action is likely not necessary for antipsychotic activity. However, a 5-HT<sub>1A</sub> agonist activity was proposed to enhance memory and cognition in schizophrenia because it was shown that (1) 5-HT<sub>1A</sub> receptors are concentrated in brain regions thought to mediate several cognitive functions (e.g., hippocampus, thalamus, cingulate cortex and PFC) (Roth *et al.*, 2004), and (2) clozapine increases dopamine release in the PFC via its 5-HT<sub>1A</sub> agonism (Rollema *et al.*, 1997). In support of this hypothesis, Sumiyoshi and colleagues reported that chronic administration of the selective 5-HT<sub>1A</sub> receptor agonist tandospirone as a co-therapy with typical antipsychotics enhanced verbal memory and executive functions in schizophrenia patients (Sumiyoshi *et al.*, 2001a, 2001b). In contrast, chronic co-administration of the 5-HT<sub>1A</sub> receptor partial agonist buspirone with atypical antipsychotics improved psychomotor speed but not memory or executive function in schizophrenia patients (Sumiyoshi *et al.*, 2007). On the other hand, tandospirone exerted negative effects on memory function in demented patients (Yasuno *et al.*, 2003), and the potent 5-HT<sub>1A</sub> agonist NAE-086 induced hallucinations and nightmares in healthy volunteers after repeated doses (Renyi *et al.*, 2001). Thus, augmentation with a 5-HT<sub>1A</sub> partial agonist for cognitive enhancement in schizophrenia seems only to be effective in combination with antipsychotics that lack 5-HT<sub>1A</sub> activity. Contrarily, atypical antipsychotics with a 5-HT<sub>1A</sub> agonistic action should not be combined with tandospirone or buspirone because this may worsen

psychotic symptoms and has no additional effects on cognition (Roth *et al.*, 2004).

In addition, clozapine has higher affinity for the 5-HT<sub>2C</sub> receptor than for the 5-HT<sub>2A</sub> receptor. Animal studies first suggested that activation of 5-HT<sub>2C</sub> receptors is inhibitory, while activation of 5-HT<sub>2A</sub> receptors is stimulatory (Martin *et al.*, 1997, 1998). This led to the conclusion that 5-HT<sub>2C</sub> receptor agonists might be antipsychotic (Abi-Dargham and Krystal, 2000). Newer data have shown that 5-HT<sub>2C</sub> receptor antagonists can directly increase dopamine release in the nucleus accumbens and PFC (Di Matteo *et al.*, 1998), while 5-HT<sub>2C</sub> receptor agonists markedly decrease dopamine and noradrenalin levels in the frontal cortex of rats (Millan *et al.*, 1998). Administration of the 5-HT<sub>2C/2A</sub> agonist m-CPP caused deterioration of positive psychotic symptoms in schizophrenia, an effect that could be prevented by the 5-HT<sub>2C/2A</sub> blocker ritanserin (Abi-Saab *et al.*, 2002). Moreover, ritanserin in combination with risperidone showed significant superiority over risperidone alone in decreasing negative symptoms in schizophrenia patients (Akhondzadeh *et al.*, 2008). These results suggest that 5-HT<sub>2C</sub> blockade may actually have beneficial effects on positive, negative and cognitive symptoms in schizophrenia (Meltzer *et al.*, 2003). In contrast, earlier work demonstrated that affinity to the 5-HT<sub>2C</sub> receptor did not distinguish typical from atypical antipsychotics (Roth *et al.*, 1992), and Meltzer *et al.* (2003) concluded that the high 5-HT<sub>2C</sub> receptor affinity of some atypical substances (e.g., clozapine, olanzapine, sertindole) roughly corresponds with their potential to produce weight gain rather than with potential antipsychotic activity. However, some

**Table 4** Affinities of selected antipsychotic drugs for 5-HT receptors expressed as pK<sub>i</sub> (the negative logarithm to base 10 of the equilibrium dissociation constant, K<sub>i</sub>, in molar concentration units)\*

\*Higher values imply a higher affinity. No value is shown if no data were available or if the pK<sub>i</sub> was below 3. All data were drawn from the IUPHAR database (Harmar *et al.*, 2009; www.iuphar-db.org).

Abbreviations: ag, agonist; ant, antagonist; pag, partial agonist; iag, inverse agonist.

clinical data did suggest that augmentation with the 5-HT<sub>2C/2A</sub> antagonists ritanserin and mianserin may have some beneficial effects, especially on negative and cognitive symptoms in schizophrenia (Lieberman *et al.*, 1998; Meltzer *et al.*, 2003; Akhondzadeh *et al.*, 2008).

5-HT<sub>3</sub> receptor antagonists have also been investigated as potential antipsychotics because clozapine has a moderate affinity for this receptor, and preclinical animal studies indicated possible antipsychotic efficacy (Lieberman *et al.*, 1998). Although an open-label and uncontrolled clinical trial demonstrated a moderate antipsychotic activity of the selective 5-HT<sub>3</sub> receptor antagonist ondansetron (DeVeau-Geiss *et al.*, 1992), these results could not be replicated in a double-blind study (Gaster and King, 1997). Also, the 5-HT<sub>3</sub> antagonist zacopride was not effective in the treatment of schizophrenia (Newcomer *et al.*, 1992), suggesting that the 5-HT<sub>3</sub> receptor is not a promising drug target in the treatment of schizophrenia.

Given that 5-HT<sub>4</sub> receptors modulate acetylcholine and GABA release, and that 5-HT<sub>4</sub> receptors are found in high densities in the frontal cortex and the hippocampus, it was suggested that modification of 5-HT<sub>4</sub> receptor activity could be helpful in improving cognition in schizophrenia. Several animal studies support this assumption, but studies in healthy human volunteers and schizophrenia patients are lacking so far (Roth *et al.*, 2004; Gray and Roth, 2007). Since atypical antipsychotic drugs are devoid of major 5-HT<sub>4</sub> receptor actions, Roth *et al.* (2004) recommended that a 5-HT<sub>4</sub> partial agonist would be potentially beneficial as add-on therapy for improving cognition in schizophrenia.

On the basis of animal studies, the 5HT<sub>6</sub> receptor was suggested to be a promising drug target to specifically improve cognition in schizophrenia as well (Meltzer *et al.*, 2003; Roth *et al.*, 2004; Gray and Roth, 2007). The 5-HT<sub>6</sub>-selective antagonist SB-271046 is currently undergoing preclinical testing as a cognitive enhancer in schizophrenia (Hatcher *et al.*, 2005; Marcos *et al.*, 2008; Da Silva Costa *et al.*, 2009). However, several typical (e.g., chlorpromazine, fluphenazine) and atypical (e.g., clozapine, olanzapine, ziprasidone and quetiapine) antipsychotics have high affinity for the 5-HT<sub>6</sub> receptor, making it unlikely that addition of a 5-HT<sub>6</sub> antagonistic drug would further improve cognition in schizophrenia patients treated with these antipsychotics (Roth *et al.*, 1994, 2004). Moreover, both 5-HT<sub>6</sub> agonists and antagonists have shown pro-cognitive properties in preclinical animal studies, but an explanation for these paradoxical effects is currently missing (Fone, 2008). Thus, further studies are needed to further understand the role of the 5-HT<sub>6</sub> receptor in the modulation of cognition and to develop 5-HT<sub>6</sub> antagonist compounds for the treatment of cognitive deficits in schizophrenia.

Both clozapine and risperidone, as well as the typical drugs chlorpromazine, fluphenazine and pimozide, have high affinity for the 5-HT<sub>7</sub> receptor (Roth *et al.*, 1994); this suggests that a 5-HT<sub>7</sub> action is not a feature of atypicality (Abi-Dargham and Krystal, 2000). Evidence primarily drawn from knockout studies in mice indicates that the 5-HT<sub>7</sub> receptor plays an important role in hippocampus-dependent functions, including learning and memory (Gray and Roth, 2007). These data warrant further investigation into the potential use of 5-HT<sub>7</sub> receptor antagonist compounds in the treatment of memory dysfunction in schizophrenia (Gray and Roth, 2007).

### ***Antipsychotic drug action and serotonin receptor occupancy***

Most of the molecular imaging studies investigating the role of receptor occupancy in antipsychotic activity by PET or SPECT have traditionally focused on the dopamine system. Here it was consistently shown that typical antipsychotics usually produce higher striatal D<sub>2</sub> receptor occupancy rates (>70 percent) than atypical antipsychotics (<70 percent) at mean therapeutic doses (Lieberman *et al.*, 1998; Kasper *et al.*, 1999; Weinberger and Laruelle, 2002). Given that the atypicals clozapine and quetiapine display the lowest rates of D<sub>2</sub> occupancy (20–67 percent) at clinically effective doses and that most of the studies could not demonstrate a linear correlation between striatal D<sub>2</sub> binding and therapeutic efficacy, striatal D<sub>2</sub> receptor occupancy rates alone cannot sufficiently explain antipsychotic activity (Kasper *et al.*, 1999; Weinberger and Laruelle, 2002). On the contrary, several studies consistently found a clear correlation between EPS and striatal D<sub>2</sub> receptor occupancy, indicating a high likelihood of EPS when D<sub>2</sub> occupancy exceeds a threshold of 80 percent (Kasper *et al.*, 1999; Weinberger and Laruelle, 2002; Zipursky *et al.*, 2007). Since at least 50–60 percent D<sub>2</sub> receptor occupancy is required to observe rapid clinical response with typical antipsychotics such as haloperidol, an optimal antipsychotic dose range resulting in 70–80 percent D<sub>2</sub> occupancy was suggested (Nordstrom *et al.*, 1993; Nyberg *et al.*, 1999; Kapur *et al.*, 2000). However, this rule does not apply to clozapine and quetiapine.

In line with the *in vivo* data (see above), most of the atypical drugs display higher 5-HT<sub>2A</sub> than D<sub>2</sub> occupancy rates when dual-tracer approaches are used (Kapur *et al.*, 1998; Nyberg *et al.*, 1999; Gefvert *et al.*, 2001; Mamo *et al.*, 2004). However, although it was suggested that the predominant 5-HT<sub>2A</sub> receptor antagonism of atypical drugs protects against EPS (Meltzer, 1999), even atypical substances such as olanzapine or risperidone cause

EPS when given in higher doses that lead to D<sub>2</sub> receptor occupancy of more than 80 percent (Kapur *et al.*, 1998; Nyberg *et al.*, 1999). Thus, occupancy of 5-HT<sub>2A</sub> receptors does not confer protection against EPS, because the threshold of D<sub>2</sub> receptor occupancy associated with EPS is not markedly reduced for atypical substances with a balanced 5-HT<sub>2A</sub>/D<sub>2</sub> receptor profile (Weinberger and Laruelle, 2002). Compared to the other atypicals, aripiprazole is an interesting exception regarding D<sub>2</sub>, 5-HT<sub>2A</sub> and 5-HT<sub>1A</sub> receptor occupancy. A recent study has shown that aripiprazole exhibits very high striatal D<sub>2</sub> occupancy (81–94 percent), lower occupancy of frontal and temporal 5-HT<sub>2A</sub> receptors (31–84 percent), and even lower occupancy at frontal and temporal 5-HT<sub>1A</sub> receptors (–2 percent to 44 percent) at doses between 10 and 30 mg in schizophrenia patients. EPS was seen only in two of four subjects with D<sub>2</sub> occupancies exceeding 90 percent (Mamo *et al.*, 2007). In accordance with the study of Bantick *et al.* (2004), who showed that clozapine did not occupy the 5-HT<sub>1A</sub> receptor at clinical doses, these data do not support an important role of the 5-HT<sub>1A</sub> receptor regarding antipsychotic activity. In sum, molecular imaging studies do not support the view that the 5-HT<sub>2A</sub> or 5-HT<sub>1A</sub> mechanism of several atypical drugs contributes significantly to their clinical superiority.

### Serotonergic challenge studies

Given that the release of several hormones, such as cortisol, prolactin and growth hormone (GH), is under monoaminergic control, the neuroendocrine challenge paradigm is suitable to investigate the functional state of central monoaminergic systems. In a hypersensitive system the stimulation of 5-HT receptors will induce augmented hormonal release, whereas in a hypoactive system increased release would be expected. If 5-HT receptors are antagonized, the reverse results are anticipated (Murphy *et al.*, 1986).

Early neuroendocrine challenge studies investigating small samples of schizophrenia patients and employing the 5-HT precursors tryptophan and 5-hydroxytryptophan (5-HTP) reported inconsistent results. Two studies reported an increased prolactin response and a blunted GH release (Cowen *et al.*, 1985; Kolakowska *et al.*, 1987). One study found decreased prolactin responses and decreased GH response only in long-term haloperidol-treated patients, whereas short-term treated patients did not differ from controls in both measures (Hoshino *et al.*, 1985). However, precursor effects are relatively muted because of their ‘upstream’ (and therefore secondary) actions on synaptic function, making these studies hard to interpret (Breier, 1995).

Challenge studies with the serotonin releaser fenfluramine (racemate or d-form) provided some conflicting results as well. Whereas an initial study reported a decreased prolactin release in chronic patients (Lerer *et al.*, 1988), two later studies found prolactin hyper-responsivity in drug-free patients (Abel *et al.*, 1996; Monteleone *et al.*, 1999). However, in a study by Monteleone *et al.* (1999), the elevated prolactin response was restricted to patients who were refractory to typical neuroleptics. In line with that, Mohr *et al.* (1998) reported that a higher prolactin response to d-fenfluramine, and therefore a higher responsiveness of the 5-HT system, was associated with poorer treatment response to haloperidol in unmedicated first-episode patients. Additionally, Sharma *et al.* (1999) found that a higher prolactin response to dl-fenfluramine was correlated with more negative symptoms. These studies also varied with regard to psychotic symptom provocation after fenfluramine: some reported no changes, while others described exacerbation of positive symptoms.

The serotonin and noradrenaline reuptake inhibitor clomipramine, which also acts as a 5-HT<sub>2</sub> receptor antagonist, provoked an increased prolactin response in drug-naïve schizophrenia patients – an effect that was positively correlated with duration of illness and negatively correlated with treatment response (Angelopoulos *et al.*, 2002). However, another study did not find changes in the prolactin release after clomipramine in patients treated with typical antipsychotics (Markianos *et al.*, 2001).

The drug m-chlorophenylpiperazine (mCPP) preferentially acts as a partial agonist at 5-HT<sub>2C</sub> receptors and as an antagonist at 5-HT<sub>2A</sub> receptors, but also binds to several other 5-HT receptor subtypes (Kahn and Wetzler, 1991). mCPP increases anxiety, body temperature and plasma levels of prolactin, cortisol, GH and ACTH, but does not provoke psychotic symptoms in healthy human volunteers (Breier, 1995). Schizophrenia patients show either blunted (Iqbal *et al.*, 1991; Maes and Meltzer, 1996) or normal prolactin response to mCPP (Kahn *et al.*, 1992; Krystal *et al.*, 1993). Moreover, mCPP has been reported to exacerbate (Iqbal *et al.*, 1991; Krystal *et al.*, 1993; Abi-Saab *et al.*, 2002), reduce (Kahn *et al.*, 1992) or have no effect on psychotic symptoms (Breier *et al.*, 1993; Owen *et al.*, 1993; Koreen *et al.*, 1997). Clozapine has been reported to block the symptom-worsening and hormone-releasing effects of mCPP; this was attributed to 5-HT<sub>2C</sub> antagonistic effects of clozapine (Breier *et al.*, 1993; Kahn *et al.*, 1993a; Krystal *et al.*, 1993; Owen *et al.*, 1993). Similar effects were shown for olanzapine (Abi-Saab *et al.*, 2002) and the 5-HT<sub>2</sub> antagonist ritanerlin (Scheepers *et al.*, 2001a).

In general, the contradictory results across the different serotonergic challenge studies point to heterogeneity

in central serotonergic sensitivity within different subpopulations of schizophrenia patients. This assumption is also supported by the consistent observation that a hypersensitive 5-HT system is associated with poor treatment response to mostly typical antipsychotics. Serotonergic challenge studies might therefore be useful for tailoring individual antipsychotic pharmacotherapy.

### Serotonin metabolites in the cerebrospinal fluid

Many studies have measured monoamine metabolite concentrations in the cerebrospinal fluid (CSF) of schizophrenia patients in order to investigate central 5-HT and dopamine turnover. Most of the early studies did not find changes in the CSF concentration of the major 5-HT metabolite 5-HIAA, but some reported decreased 5-HIAA CSF levels in schizophrenia (for review and references, see Bleich *et al.*, 1991). A more recent meta-analysis and a recent study with a large sample of schizophrenia patients have supported the view that mean 5-HIAA concentrations in the CSF are generally relatively unaltered in schizophrenia patients (Tuckwell and Koziol, 1996; Wieselgren and Lindstrom, 1998). In contrast, another meta-analysis has indicated that CSF levels of the main metabolite of dopamine, homovanillic acid (HVA), are lowered in schizophrenia patients (Tuckwell and Koziol, 1993); this finding was confirmed by a more recent study investigating 90 schizophrenia patients and 47 healthy controls (Wieselgren and Lindstrom, 1998). Studies linking specific characteristics of the illness with 5-HIAA CSF levels have shown that low 5-HIAA concentrations are associated with advanced brain atrophy (Nyback *et al.*, 1983; Potkin *et al.*, 1983; Jennings *et al.*, 1985; Losonczy *et al.*, 1986), more prominent negative symptoms (Pickar *et al.*, 1986; Csernansky *et al.*, 1990), and failure to activate the PFC during the Wisconsin Card Sorting Test (Weinberger *et al.*, 1988). However, all of these measures have been found to be associated with decreased HVA CSF levels as well (Nyback *et al.*, 1983; Potkin *et al.*, 1983; Jennings *et al.*, 1985; Losonczy *et al.*, 1986; Pickar *et al.*, 1986; Csernansky *et al.*, 1990; Weinberger *et al.*, 1988; Scheepers *et al.*, 2001b). However, one of the best replicated findings in biological psychiatry is the strong intercorrelation of monoamine metabolites in the CSF, which possibly could be explained by similar transport mechanisms of all monoamines (Hsiao *et al.*, 1993). This idea has led to the approach of calculating HVA/5-HIAA concentration ratios to investigate the relation of serotonergic and dopaminergic activity in schizophrenia (Hsiao *et al.*, 1993). Lewine *et al.* (1991) demonstrated, for example, that the HVA/5-HIAA ratio was a better predictor of the extent of brain atrophy than HVA or 5-HIAA CSF

levels alone (see also Nyback *et al.*, 1983). Additionally, while 5-HIAA and HVA levels alone could not predict treatment outcome, a low HVA/5-HIAA CSF ratio was significantly associated with better response to clozapine and typical antipsychotics in several studies (Pickar *et al.*, 1992; Kahn *et al.*, 1993b; Risch and Lewine, 1993; Szymanski *et al.*, 1993; Lieberman *et al.*, 1994; Risch, 1995). These results suggested that the antipsychotic effect is associated with changing dopamine function relative to 5-HT function, rather than changing dopamine or 5-HT function *per se* (Scheepers *et al.*, 2001b). However, at least two studies failed to find a predictive value of the HVA/5-HIAA CSF ratios regarding treatment response to olanzapine, clozapine or haloperidol treatment (Jacobsen *et al.*, 1997; Scheepers *et al.*, 2001b), while one study reported a worse long-term outcome in patients with a low HVA/5-HIAA CSF ratio (Wieselgren and Lindstrom, 1998). These discrepancies may be explained due to differences in patient populations, duration of treatment, method of analysis or criteria of response.

Surprisingly, several investigations demonstrated that neither typical nor atypical antipsychotics changed 5-HIAA CSF levels in the course of treatment, although many of these substances strongly affect the 5-HT system (van Kammen *et al.*, 1986; Kahn *et al.*, 1994; Jacobsen *et al.*, 1997; Wieselgren and Lindstrom, 1998; Scheepers *et al.*, 2001b). These results put the idea that 5-HIAA CSF concentrations are a valid marker of the central 5-HT turnover somewhat into question. Moreover, it was suggested that 5-HIAA concentrations may not mirror 5-HT metabolism in the whole brain, but rather reflect turnover in specific brain regions such as frontal cortices and the striatum (Scheepers *et al.*, 2001b). On the contrary, typical antipsychotics seemed to consistently elevate HVA CSF levels and HVA/5-HIAA CSF ratios, while atypical substances did not (Hsiao *et al.*, 1993; Kahn *et al.*, 1993b; Wieselgren and Lindstrom, 1998; Scheepers *et al.*, 2001b).

In sum, investigations on 5-HT metabolite levels in the CSF in schizophrenia are hard to interpret because it is not clear what the specific neuronal substrate of 5-HIAA CSF levels is. However, there is some consistency in the data showing that at least a subpopulation of patients display changes in global 5-HT and dopamine turnover, and these patients may respond differentially to antipsychotics than other subpopulations.

### Platelet studies

Human blood platelets have been proposed as a peripheral model of central 5-HT function because platelets are neuroectodermal derivatives that share several biochemical

and morphological characteristics with 5-HT synapses (Bleich *et al.*, 1991).

Most of the studies investigating platelet or whole blood 5-HT concentrations in schizophrenia patients found elevated values, although there have also been some contradictory results (for review, see Bleich *et al.*, 1991; Iqbal and van Praag, 1995). The increase in peripheral 5-HT concentrations reported in the early studies was apparently not an artifact of medication, as no *in vivo* effect of antipsychotics on platelet 5-HT could be demonstrated (Bleich *et al.*, 1991). On the contrary, accumulating evidence suggests that treatment with clozapine and other atypical and typical antipsychotics increases 5-HT plasma levels in schizophrenia patients (Joseph *et al.*, 1977; Schulz *et al.*, 1997; Fleischhaker *et al.*, 1998; van der Heijden *et al.*, 2004; Ertugrul *et al.*, 2007). These findings suggest that antipsychotics still have an impact on peripheral 5-HT concentrations, and indicate that medication may have indeed influenced previous results.

The findings regarding platelet 5-HT uptake are less consistent. The numbers of studies reporting reduced or unchanged platelet 5-HT uptake are more or less equal (for review, see Bleich *et al.*, 1991; Iqbal and van Praag, 1995). However, Arora and Meltzer (1983) have convincingly demonstrated that a 2-week treatment with chlorpromazine significantly decreased platelet 5-HT uptake in schizophrenia patients and healthy controls. Thus, previous findings of reduced platelet 5-HT uptake in schizophrenia patients are likely explained by acute or residual antipsychotic treatment effects. Moreover, several studies investigating [<sup>3</sup>H]imipramine binding sites on platelets, which have been suggested as another measure of 5-HT uptake or transport, predominantly yielded no differences between normals and schizophrenia patients (for review, see Bleich *et al.*, 1991; Iqbal and van Praag, 1995).

Platelet 5-HT<sub>2A</sub> receptors are identical to brain 5-HT<sub>2A</sub> receptors in terms of their pharmacological properties (Ostrowitzki *et al.*, 1993). Although Arora and Meltzer (1983) detected an increased number of 5-HT<sub>2A</sub> receptors on platelets from suicidal schizophrenia patients, a newer study reported increased platelet 5-HT<sub>2A</sub> receptor density in chronic, medication-free patients with schizophrenia (Arranz *et al.*, 2003). Given that treatment with risperidone strongly increased platelet 5-HT<sub>2A</sub> receptor density, Arranz *et al.* (2003) concluded that the increased platelet 5-HT<sub>2A</sub> receptor density in their drug-free sample was a residual drug effect caused by previous antipsychotic treatment. Additionally, these authors reported recently that low baseline platelet 5-HT<sub>2A</sub> receptor levels may predict clinical response to olanzapine in a group of antipsychotic-naïve schizophrenia patients (Arranz *et al.*, 2007).

The activity of platelet monoamine oxidase (MAO) has also been studied in schizophrenia, demonstrating results similar to platelet 5-HT<sub>2A</sub> receptor density. Although there are some indications of decreased platelet MAO activity in at least some subgroups of schizophrenia patients (Zureick and Meltzer, 1988), it could not be excluded that this effect is primarily caused by antipsychotic treatment (DeLisi *et al.*, 1981; Ohuoha *et al.*, 1993; Ertugrul *et al.*, 2007).

It should be noted that the changes of serotonergic markers found in platelets are largely in the opposite direction to the alterations that have been found in more centrally relevant 5-HT measures in schizophrenia patients (e.g., decreased 5-HT in CSF and brain tissue vs increased 5-HT in blood and platelets; decreased 5-HT receptors in several brain regions vs increased 5-HT<sub>2A</sub> receptor density in platelets). In addition, treatment with antipsychotics has also had mostly opposite effects on platelet and brain 5-HT markers, respectively. These facts suggest that platelets are not an ideal model for brain 5-HT function (Roth and Meltzer, 2000).

### Neurotrophic role of serotonin in the developmental disorder schizophrenia

As reviewed by Whitaker-Azmitia in Chapter 3.1 of this volume, serotonin plays a major role at several stages of neuroplasticity. During embryogenesis, the serotonin system is one of the first neurotransmitter systems that innervates brain structures and demonstrates functional activity. In this phase, serotonin acts as a growth factor that influences neuronal and glial morphology, and connectivity. Some of these effects are direct, whereas some others are mediated by the interaction with further chemical messengers (such as brain-derived neurotrophic factor (BDNF) or S100β) and other neurotransmitter systems (such as dopamine, GABA and glutamate). However, postnatal serotonin also influences the formation and degradation of synapses and axon terminals, indicating that serotonin is important not only for neuronal development but also for the preservation and maintenance of normal function in the adult brain (see also Sodhi and Sanders-Bush, 2004).

Accumulating evidence from several domains suggests that schizophrenia could be a neurodevelopmental disorder that is – at least in part – caused by aberrant early brain development:

1. Many schizophrenia patients exhibit delayed developmental milestones in childhood, including cognitive, motor and behavioral abnormalities, which indicates abnormal brain function prior to diagnosis of schizophrenia.

2. Obstetric complications and prenatal infections increase the risk for schizophrenia.
3. *Post-mortem* studies have not found indicators for neurodegenerative processes such as gliosis or loss of neurons in the brain of schizophrenia patients.
4. Several anatomical and functional disruptions are associated with exacerbation of schizophrenia in adulthood, and these disruptions can be simulated in developmental animal models (Marenco and Weinberger, 2000; Miyamoto *et al.*, 2003).

As suggested by Murray *et al.* (1992), aberrant developmental processes may play a major role, especially in the congenital subform of schizophrenia that shows a gradual increase in behavioral disturbances until the disorder is diagnosed in adolescence or early adulthood. Maynard and colleagues (2001) have proposed a two-hit hypothesis of schizophrenia. According to their suggestion, a lesion occurring in early neurodevelopment (first hit) and caused by a genetic load or adverse embryonic and perinatal events, in combination with a second hit arising from hormonal events, excitotoxicity, psychosocial stress or oxygen radical formation, may cause schizophrenia.

Immunocytochemical and ultrastructural *post-mortem* studies have demonstrated neurocellular alterations in schizophrenia, such as decreased neuronal size, increased cellular packing density, fewer dendritic spines and synapses, and distortions in neuronal orientation (for review, see Arnold, 1999). The abnormalities in the cytoarchitecture, such as neuronal disarray, heterotopias and malpositioning, indicate disruption of proliferation or migration during the gestational period (Miyamoto *et al.*, 2003). In accordance, it was consistently shown that the expression of reelin, a glycoprotein that regulates neuronal migration, is strongly decreased in schizophrenia patients (Impagnatiello *et al.*, 1998; Guidotti *et al.*, 2000). Moreover, anatomical studies found enlargements of the lateral and third ventricles in conjunction with a decrease in cortical volume, especially within the hippocampal formation and the amygdala; additionally, subcortical structures appear to be reduced in size, including the thalamus and striatum (for review, see Sodhi and Sanders-Bush, 2004). It is unlikely that these macrostructural alterations are simply caused by neurodegenerative processes, because some of them have also been shown at a prodromal state of schizophrenia (Wood *et al.*, 2003; Morey *et al.*, 2005; Jessen *et al.*, 2006), and *post-mortem* studies did not find gliosis and neuronal cell loss. Thus, these anatomical and cytoarchitectural changes are likely to arise during brain maturation.

Several lines of evidence suggest that abnormalities in brain development may contribute to the pathogenesis of schizophrenia in a subset of patients. Moreover, we know

that serotonin plays an important role in neurogenesis and neuronal plasticity. However, future studies will have to determine whether genetic or early developmental insults could alter the serotonin system in a manner that leads to sustained neuronal changes during brain development, which consequently induces the symptoms of schizophrenia.

### Serotonin–glutamate interactions

NMDA antagonists such as phencyclidine (PCP) and ketamine produce effects in humans that closely mimic the symptoms of schizophrenia (Javitt and Zukin, 1991; Krystal *et al.*, 1994). Microdialysis studies have demonstrated that ketamine and PCP increase glutamate outflow in PFC (Moghaddam *et al.*, 1997; Adams and Moghaddam, 1998). Potentially related to this effect is evidence that increases in glutamatergic activity may contribute to the psychotomimetic and behavioral effects of these drugs. Indeed, diminution of PCP-induced glutamate release by activation of metabotropic glutamate 2/3 (mGlu<sub>2/3</sub>) receptors attenuates the effects of PCP on locomotor activity and stereotypy (Moghaddam and Adams, 1998). Other agents that decrease glutamate release also reduce the behavioral effects of PCP and ketamine (Anand *et al.*, 2000; Idris *et al.*, 2005). In each of these cases the actions of the released glutamate would presumably be on non-NMDA glutamate receptors – AMPA, kainate, or metabotropic – since PCP and ketamine block NMDA receptor functions. The involvement of glutamate release in the psychotomimetic effects of NMDA antagonists is consistent with the hypothesis that dysfunction of glutamatergic systems underlies the psychopathology of schizophrenia (Javitt and Zukin, 1991; Halberstadt, 1995; Jentsch and Roth, 1999).

Electrophysiological evidence demonstrates that LSD and other serotonergic hallucinogens can modulate cellular responses to glutamate (Rahman and Neuman, 1993; Arvanov *et al.*, 1999). Recent studies indicate that hallucinogens increase the release of glutamate in neocortex (Scruggs *et al.*, 2003; Muschamp *et al.*, 2004). Activation of 5-HT<sub>2A</sub> receptors by 5-HT and the hallucinogen 2,5-dimethoxy-4-iodoamphetamine (DOI) produces an enhancement of the frequency and amplitude of spontaneous excitatory postsynaptic potentials/currents (EPSPs/EPSCs) in most layer V pyramidal cells of PFC (Aghajanian and Marek, 1997; Lambe *et al.*, 2000; Klodzinska *et al.*, 2002; Benneyworth *et al.*, 2007); this effect is mediated by increased glutamate efflux and subsequent activation of AMPA receptors (Zhang and Marek, 2008). There is also evidence that 5-HT- and DOI-induced EPSCs are suppressed by activation of mGlu<sub>2/3</sub> receptors,

and augmented by mGlu<sub>2/3</sub> receptor blockade (Marek *et al.*, 2000; Klodzinska *et al.*, 2002; Benneyworth *et al.*, 2007). Although it is generally accepted that 5-HT<sub>2A</sub> receptor activation increases the terminal release of glutamate in PFC, there has been some controversy regarding the source of these glutamatergic terminals. Based on evidence that lesions of the medial thalamus attenuate 5-HT-induced EPSCs, Marek and colleagues have argued that thalamocortical afferents are involved (Marek *et al.*, 2001). However, Béique *et al.* (2007) recently identified a subpopulation of pyramidal cells in the deep layers of PFC that are excited by 5-HT<sub>2A</sub> receptor activation, indicating that the spontaneous EPSCs evoked by 5-HT may be a product of PFC recurrent network activity.

As was found with PCP, the behavioral effects of serotonergic hallucinogens are attenuated by activation of mGlu<sub>2/3</sub> receptors. The ability of DOI to induce the head-twitch response in mice and rats is suppressed by the selective mGlu<sub>2/3</sub> agonists LY354740 and LY379268; conversely, the selective mGlu<sub>2/3</sub> antagonist LY341495 enhances the frequency of DOI-induced head-twitch (Gewirtz and Marek, 2000; Klodzinska *et al.*, 2002). Likewise, the mGlu<sub>2</sub> positive allosteric modulator biphenyl-indanone A inhibits the head-twitch response induced by the hallucinogen (–)-2,5-dimethoxy-4-bromoamphetamine (DOB) (Benneyworth *et al.*, 2007). It has also been shown that the discriminative stimulus effects of LSD are potentiated by LY341495 and partially antagonized by LY379268 (Winter *et al.*, 2004). The ability of mGlu<sub>2/3</sub> receptor ligands to alter the behavioral response to DOI, DOB and LSD indicates that the behavioral effects of hallucinogens are linked to their ability to increase glutamate release.

Taken together, the aforementioned findings demonstrate that NMDA receptor antagonists and serotonergic hallucinogens increase glutamate release, and it has been suggested that the glutamatergic system may represent a common final pathway for their psychotomimetic effects (Vollenweider and Geyer, 2001). This view is consistent with the fact that both ketamine and psilocybin produce metabolic hyperfrontality (Vollenweider *et al.*, 1997a, 1997b), and have somewhat similar effects on perception and cognition (Vollenweider and Geyer, 2001). Additional support for the convergence of serotonergic and glutamatergic systems is derived from the finding that the behavioral effects of hallucinogens are potentiated by co-administration of NMDA antagonists (Dall'Olio *et al.*, 1999; Winter *et al.*, 2000, 2004; Zhang and Marek, 2008). Recently, evidence has emerged that mGlu<sub>2</sub> and 5-HT<sub>2A</sub> receptors are co-localized in cortical neurons, where they may form functional complexes (Gonzalez-Maesó *et al.*, 2008). The existence of a mGlu<sub>2</sub>/5-HT<sub>2A</sub> receptor complex is intriguing in light of a recent report that a produg

for a selective mGlu<sub>2/3</sub> agonist possesses significant anti-psychotic efficacy in schizophrenic patients (Patil *et al.*, 2007).

## Conclusions and future directions

As reviewed above, considerable evidence derived from converging methods suggests that schizophrenia patients display abnormalities in serotonergic function. Nevertheless, different approaches intended to measure identical biological markers have frequently produced contradictory results (e.g., autoradiographic *post-mortem* studies vs PET studies). In particular, results from peripheral measures (CSF, platelets, blood, hormone response) have often not matched findings based upon more central parameters of serotonin function (receptor density, brain levels of 5-HT and metabolites). Moreover, it has repeatedly been shown that some alterations of the 5-HT system reported in schizophrenia patients could be explained by chronic treatment with antipsychotic drugs. Despite some methodological reservations and the many contradictory results, there is accumulating evidence that the 5-HT<sub>1A</sub> and 5-HT<sub>2A</sub> receptor subtypes play an especially important role in schizophrenia. *Post-mortem* studies and some PET data suggest that schizophrenia patients display an increase of 5-HT<sub>1A</sub> and a decrease of 5-HT<sub>2A</sub> receptors, especially in the PFC. Genetic variations of the 5-HT<sub>2A</sub> receptor (and perhaps also of the 5-HT<sub>1A</sub> receptor) appear to contribute to the risk of developing schizophrenia and the response to antipsychotic treatment. These genetic variations also appear to be associated with endophenotypic markers of schizophrenia, such as sensorimotor gating. Hallucinogenic 5-HT<sub>2A</sub> agonists produce some schizophrenia-like symptoms, and also mimic several endophenotypes of schizophrenia. In contrast, the hypothesis that a serotonergic mechanism is necessary for the claimed therapeutic superiority of the so-called atypical antipsychotics is not well supported by the data so far, because a 5-HT antagonistic action seems to be not sufficient for an antipsychotic effect (at least on the level of large and heterogeneous populations of schizophrenia patients). Nevertheless, 5-HT<sub>1A</sub> agonists and 5-HT<sub>2C</sub> antagonists may have some beneficial effects, particularly on cognition and negative symptoms. Additionally, agents acting at other 5-HT receptor subtypes (5-HT<sub>4</sub>, 5-HT<sub>6</sub>, 5-HT<sub>7</sub>) may have some pro-cognitive effects in schizophrenia patients.

The highly contradictory results regarding serotonergic alterations in schizophrenia might have two origins:

1. Alterations of the serotonin system are not sufficient to explain the full picture of schizophrenia. This view is supported by the fact that other transmitter systems

(e.g., dopamine, GABA, glutamate, acetylcholine) and biochemical substrates (e.g., reelin, BDNF, synaptophysin, SNAP-25 and complexin II) are also affected in schizophrenia patients.

2. Not all but only a subpopulation of the patients within the broad disease cluster schizophrenia display changes in serotonin function. This assumption is supported by several studies showing that some patients better respond to serotonergic antipsychotic drugs than other patients, that some alterations of the 5-HT systems at baseline could predict treatment response, and that serotonergic challenges induce a broad range of reactions ranging from improvement to worsening of symptoms, pointing to substantial heterogeneity of central serotonergic activity.

The 5-HT system is probably only one piece of the enigmatic mosaic of the multifactorial causation of the group of schizophrenia spectrum disorders. Specific polymorphisms within the 5-HT system might influence – for example, the expression of serotonin receptors during neurogenesis – and these changes could have an impact on later brain maturation and 5-HT function. However, only in combination with further neurodevelopmental ‘hits’ (such as pre- and postnatal infections, stressful events or drug use during pregnancy, obstetric complications, a stressful adolescence or further critical life events) and other genetic variations (DISC1, VMAT1, GRIN2) could the symptom pattern of a schizophreniform disorder arise.

Future studies should devote more attention to the demarcation of subpopulations of schizophrenia patients exhibiting specific changes of the 5-HT system, who could then be successfully treated with specific serotonergic drugs. These subpopulations should be characterized not only by distinct biological markers but also by a more precise psychopathological description. Moreover, the behavioral consequences of genetic variations within the 5-HT system or of pharmacological manipulations of the system might help us to better understand disturbed brain functions of schizophrenia patients. Finally, recent preclinical data suggest that also alterations in the interaction between the serotonin and the glutamate system might have an influence on the development and the symptoms of schizophrenia. These interactions should be further investigated in healthy humans and schizophrenia patients.

# Serotonin and Serotonin Receptors in Hallucinogen Action

Adam L. Halberstadt<sup>1</sup> and David E. Nichols<sup>\*,2</sup>

<sup>1</sup>*Department of Psychiatry, University of California, San Diego, La Jolla, California*

<sup>2</sup>*Department of Medicinal Chemistry and Molecular Pharmacology, School of Pharmacy – RHPH, Purdue University, West Lafayette, Indiana*

**Abstract:** Hallucinogens are a class of substances that induce profound changes in perception and cognition. A closely related drug, 3,4-methylenedioxymethamphetamine (MDMA), produces euphoria and a feeling of empathy, with minimal sensory distortion. Both of these classes of substances produce their effects by interacting with the serotonergic system. This chapter will review the receptor interactions that contribute to the behavioral effects of serotonergic hallucinogens and MDMA. In rodents, the behavioral effects of hallucinogens such as lysergic acid diethylamide (LSD), psilocybin and mescaline are primarily mediated by activation of 5-HT<sub>2A</sub> receptors. There is evidence, however, that 5-HT<sub>1A</sub> receptors, 5-HT<sub>2C</sub> receptors and dopamine receptors may play a secondary role. The molecular requirements for interaction of hallucinogens with the 5-HT<sub>2A</sub> receptor are well-defined on the basis of structure–activity relationships. By contrast with the hallucinogens, MDMA is a potent releaser of monoamines that has complex effects on serotonergic, dopaminergic and noradrenergic systems. In recent years, psilocybin and MDMA have been administered to human volunteers in controlled clinical trials. Human studies confirm that the 5-HT<sub>2A</sub> receptor plays a primary role in mediating the subjective effects of psilocybin, whereas the effects of MDMA are largely attributable to carrier-mediated release of serotonin. These findings emphasize the importance of clinical investigation of hallucinogenic drugs. Additionally, there is a growing consensus that these drugs are likely to show therapeutic efficacy in the treatment of certain psychiatric disorders.

**Keywords:** 5-HT<sub>2A</sub> receptor, behavior, drug discrimination, entactogen, hallucinogen, head twitch, locomotor activity, MDMA, psychedelic, prepulse inhibition.

## Introduction

Hallucinogenic drugs have been used by humans for thousands of years to diagnose and cure disease, induce mystical and spiritual states, and produce euphoria and inebriation (Schultes and Hofmann, 1980). Typically, these drugs have been derived from botanical sources. Some examples include the mescaline-containing peyote

cactus (*Lophophora williamsii*), which is legally used in the United States by members of the Native American Church; *teonanácatl* mushrooms (a species of *Psilocybe* containing psilocybin and psilocin), which have a history of ceremonial use in Mexico; and *ayahuasca*, an infusion or decoction prepared from the bark of  $\beta$ -carboline-containing species of *Banisteriopsis* to which admixture plants containing *N,N*-dimethyltryptamine (DMT) are typically added. Modern scientific investigation of the hallucinogens began with the identification of mescaline as the active principal of peyote by Arthur Heffter in 1897.

The discovery of the potent hallucinogenic effects of lysergic acid diethylamide (LSD) by Albert Hoffmann in 1943 markedly increased scientific interest in these substances.

The publication of the first description of the hallucinogenic effects of LSD (Stoll, 1947) coincided with the initial isolation and characterization of serotonin (5-HT) (Rapport *et al.*, 1948). In 1953, Gaddum reported that LSD antagonized the contractile effect of 5-HT on the isolated uterine smooth muscle (Gaddum, 1953). It was soon recognized, however, that LSD acts as a 5-HT agonist in some assay systems (Shaw and Woolley, 1956). It is now widely accepted that LSD and other hallucinogens are agonists or partial agonists at 5-HT receptors (Glennon, 1990).

The psychological effects produced by hallucinogens are highly subjective, usually including changes in thought and mood, depersonalization, and perceptual alterations that may include visual hallucinations, synesthesias and tactile sensations. The effects of serotonergic hallucinogens are distinguishable from those of other drug classes such as dissociative anesthetics (e.g., phencyclidine, ketamine),  $\kappa$ -agonists (e.g., salvinorin A), and cannabinoids, which produce some hallucinogen-like effects.

Soon after the discovery of LSD it was recognized that there are similarities between the effects of hallucinogens and the symptomatology of schizophrenia, and LSD and mescaline were used experimentally to produce a model psychosis. There is now renewed interest in the possibility that hallucinogens may be useful therapeutic drugs, and the efficacy of psilocybin in the treatment of obsessive-compulsive disorder and as an anxiolytic in terminal cancer patients has been investigated in clinical trials (Biello, 2006; Moreno *et al.*, 2006). It also has been claimed that 3,4-methylenedioxymethamphetamine (MDMA, 'Ecstasy') has value as an adjunct to psychotherapy. MDMA produces mood elevation and an increased sense of empathy with little sensory disruption. The effects of MDMA are distinct from those typically produced by hallucinogens, however, and it has been proposed that MDMA is an entactogen, a distinct class of drugs (Nichols, 1986).

The mechanism of action of hallucinogens and entactogens such as MDMA has been the subject of intense investigation. This chapter will review the receptor interactions that contribute to the behavioral effects of hallucinogens and MDMA.

### Receptors mediating the behavioral effects of hallucinogens in animals

#### 5-HT<sub>2A</sub> receptor

The 5-HT<sub>2A</sub> receptor is a G<sub>q/11</sub>-coupled receptor that is linked to the phosphoinositide hydrolysis signaling

cascade (Nichols and Nichols, 2008). Members of both the indoleamine and phenylalkylamine classes of hallucinogens bind to 5-HT<sub>2A</sub> receptors with high affinity. Phenylalkylamine hallucinogens such as 2,5-dimethoxy-4-methylamphetamine (DOM), 2,5-dimethoxy-4-iodoamphetamine (DOI), and 2,5-dimethoxy-4-bromoamphetamine (DOB) are highly selective for 5-HT<sub>2</sub> receptor subtypes (Titeler *et al.*, 1988; Pierce and Peroutka, 1989), and there is a general consensus in the literature that the behavioral effects of hallucinogens are primarily mediated by the 5-HT<sub>2A</sub> receptor (Nichols, 2004).

#### Drug discrimination

Much of what is known about the mechanism of action of hallucinogenic drugs has been derived from drug discrimination studies. Rats can be trained to discriminate hallucinogens (including LSD, mescaline, DOM, DOI, DOB, DPT, psilocybin and 5-methoxy-DMT (5-MeO-DMT) from saline using two-lever operant procedures (Hirschhorn and Winter, 1971; Glennon *et al.*, 1982). Cross-generalization occurs between these training drugs, indicating that they produce similar interoceptive stimulus effects. By contrast, members of other drug classes reliably fail to evoke hallucinogen-like stimulus effects (Glennon *et al.*, 1982; Appel and Cunningham, 1986).

Glennon and colleagues first proposed in 1983 that the behavioral effects of hallucinogens are mediated by activation of 5-HT<sub>2</sub> receptors (Glennon *et al.*, 1983). This proposal was based on the finding that the high-affinity, selective 5-HT<sub>2</sub> antagonists pirenperone and ketanserin are highly effective antagonists of the discriminative stimulus properties of DOM and LSD (Colpaert *et al.*, 1982; Colpaert and Janssen, 1983), and of DOM-stimulus generalization to LSD, mescaline, and 5-MeO-DMT (Glennon *et al.*, 1983). It was subsequently demonstrated that a robust linear correlation ( $r = 0.938$ ) exists between the 5-HT<sub>2</sub> affinities of a series of phenylalkylamine hallucinogens and their ED<sub>50</sub> values for substitution in animals trained with DOM (Glennon *et al.*, 1984). An antagonist correlation analysis confirmed that there is a strong correlation between the 5-HT<sub>2A</sub> affinity of a series of 5-HT antagonists and their potencies for blocking LSD stimulus generalization to R-(−)-DOM (Fiorella *et al.*, 1995). Additionally, stimulus control in animals trained with LSD (Winter *et al.*, 2004), DOI (Smith *et al.*, 1999; Schreiber *et al.*, 1994) and DOM (Li *et al.*, 2007) is blocked by M100907, a highly selective 5-HT<sub>2A</sub> antagonist. Taken together, these findings demonstrate that interactions with the 5-HT<sub>2A</sub> receptor are required for hallucinogens to induce discriminative stimulus effects.

### *Head-twitch response*

Hallucinogens evoke a variety of stereotypical motor responses in laboratory animals, including ear scratch in mice, head twitch in mice and rats, reciprocal hindleg body scratch in gerbils, limb flicks and abortive grooming in cats, and limb jerks in primates. The head-twitch response (HTR), which in mice consists of a paroxysmal rotational movement of the head (Corne and Pickering, 1967), is one of the best characterized of the hallucinogen-induced stereotypies. Administration of hallucinogens to rats induces an analogous behavior ('wet-dog shakes') that typically involves not only the head but also the neck and trunk. There is extensive evidence that the 5-HT<sub>2A</sub> receptor mediates the hallucinogen-induced HTR. The first evidence for a linkage between 5-HT<sub>2</sub> receptors and the HTR induced by hallucinogens was the finding that the potencies of 19 5-HT antagonists to block the mescaline HTR is significantly correlated ( $r = 0.88$ ) with their 5-HT<sub>2</sub> affinity (Leysen *et al.*, 1982). Similar findings were later reported for the HTR induced by DOI (Schreiber *et al.*, 1995). It was also demonstrated that ketanserin blocks the HTR to DOI (Darmani *et al.*, 1990). Although ketanserin is an antagonist at 5-HT<sub>2A</sub> and 5-HT<sub>2C</sub> receptors, the fact that the HTR to DOI is completely blocked by M100907, but not by the highly selective 5-HT<sub>2C</sub> antagonist SB 242,084 confirmed that the behavior is mediated by the 5-HT<sub>2A</sub> receptor and not by the 5-HT<sub>2C</sub> receptor (Vickers *et al.*, 2001). Further evidence for a link between 5-HT<sub>2A</sub> receptors and head twitch was provided by the recent finding that the ability of LSD, DOI, DOM, DOB, mescaline and psilocin to induce the HTR is abolished in 5-HT<sub>2A</sub><sup>-/-</sup> knockout mice (González-Maeso *et al.*, 2007).

### *Exploratory and investigatory behavior*

Measures of unconditioned locomotor activity are frequently used to assess compounds for stimulant or depressant effects. Tests of hallucinogens using conventional open-field measures, however, produce inconsistent results and fail to distinguish the effects of hallucinogens from those of non-hallucinogenic agents (Brimblecombe, 1963; Cohen and Wakeley, 1968; Kabes *et al.*, 1972; Silva and Calil, 1975). Given the complexity of the effects of hallucinogens, it is not surprising that the locomotor paradigm produces inconclusive findings because it does not provide a qualitative assessment of behavior and does not measure whether there are changes in sensitivity to environmental stimuli. The Behavioral Pattern Monitor (BPM), a combination of activity and holeboard chambers, was designed to overcome the shortcomings of open-field measurements (Geyer, 1990). The BPM provides both quantitative and qualitative measures of

unconditioned locomotor and investigatory activity in rats, and can be used to assess animals for changes in responsiveness to environmental stimuli.

Hallucinogens produce a characteristic profile of behavioral effects in the BPM. When phenylalkylamine (mescaline, DOM, DOI and DOET) and indolealkylamine (psilocin, DMT and 5-MeO-DMT) hallucinogens are tested in a novel environment, they decrease locomotor activity and investigatory behaviors (rearings and hole-pokes) and increase avoidance of the center of the chamber (Geyer *et al.*, 1979; Adams and Geyer, 1985a; Wing *et al.*, 1990). These effects are not observed when animals are tested in a familiar environment, and have been attributed to exacerbation of the neophobia and agoraphobia normally exhibited by rats. LSD has similar effects on investigatory behavior and center entries (Adams and Geyer, 1985b), but it produces a biphasic locomotor pattern with activity initially suppressed and then increasing as time progresses (Mittman and Geyer, 1991).

Most of the effects of DOI in the BPM paradigm are blocked by M100907 but not by the 5-HT<sub>2C/2B</sub> antagonist SER-082, and are therefore likely mediated by activation of 5-HT<sub>2A</sub> receptors (Krebs-Thomson *et al.*, 1998). Mechanistically, the effect of the indoleamines in the BPM is more complex. For example, both the mixed 5-HT<sub>1/3</sub>-adrenergic antagonist propranolol (Mittman and Geyer, 1991) and the selective 5-HT<sub>1A</sub> antagonist WAY-100635 (Krebs-Thomson and Geyer, 1996) block the initial suppression of locomotor activity induced by LSD, whereas LSD-induced hyperactivity is blocked by M100907 (Ouagazzal *et al.*, 2001) and the 5-HT<sub>2</sub> antagonist ritanserin (Mittman and Geyer, 1991). The effects of 5-MeO-DMT are antagonized by WAY-100635 but not by M100907 (Krebs-Thomson *et al.*, 2006), indicating that they are mediated by 5-HT<sub>1A</sub> receptors. However, when 5-MeO-DMT is administered in combination with a MAO-A inhibitor such as harmaline or clorgyline, it produces LSD-like late hyperactivity that is completely blocked by the 5-HT<sub>2A</sub>-selective antagonist MDL 11,939 (Halberstadt *et al.*, 2008). In summary, the effects of LSD and 5-MeO-DMT in the BPM are mediated by both 5-HT<sub>1A</sub> and 5-HT<sub>2A</sub> receptors.

### *Prepulse inhibition of startle*

Acoustic startle responses are attenuated when preceded by a weak prestimulus, a phenomenon known as prepulse inhibition (PPI). PPI serves as an operational measure of sensorimotor gating and has been found to be deficient in patients with a variety of psychiatric illnesses, including schizophrenia. Hallucinogens, including LSD, DOI, DOB and 5-MeO-DMT, disrupt PPI in rats (Rigdon and Weatherspoon, 1992; Sipes and Geyer, 1994; Johansson

*et al.*, 1995; Ouagazzal *et al.*, 2001). The decrease in PPI induced by DOI and LSD is blocked by M100907 but not by SB 242,084 or SER-082 (Sipes and Geyer, 1995; Ouagazzal *et al.*, 2001), demonstrating the involvement of 5-HT<sub>2A</sub> receptors. Compared with DOI and LSD, the mechanism for the effect of 5-MeO-DMT on PPI is more complex and involves interactions with both 5-HT<sub>1A</sub> and 5-HT<sub>2C</sub> receptors (Krebs-Thomson *et al.*, 2006).

### 5-HT<sub>2C</sub> receptor

Phenylalkylamine and indoleamine hallucinogens bind to 5-HT<sub>2C</sub> receptors with high affinity, and are relatively non-selective for 5-HT<sub>2A</sub> versus 5-HT<sub>2C</sub> receptors (Nelson *et al.*, 1999; Porter *et al.*, 1999). The discovery that hallucinogens interact with 5-HT<sub>2C</sub> receptors confounded the hypothesis that activation of 5-HT<sub>2A</sub> receptors is the primary mechanism by which LSD-like drugs act (Glennon *et al.*, 1984). This hypothesis was proposed prior to the discovery of 5-HT<sub>2C</sub> sites, and was partially based on evidence demonstrating that ketanserin and other classical 5-HT<sub>2A</sub> antagonists block the behavioral effects of hallucinogens in various animal paradigms. Unfortunately, those serotonin antagonists are now known to act at both 5-HT<sub>2A</sub> and 5-HT<sub>2C</sub> sites. The potent action of hallucinogens at 5-HT<sub>2A</sub> and 5-HT<sub>2C</sub> receptors has led authors to speculate that hallucinogenesis may be mediated by interactions with both of these receptor populations (Titeler *et al.*, 1988; Glennon, 1990). In fact, Sanders-Bush and others have gone so far as to suggest that 5-HT<sub>2C</sub> receptor occupation plays a primary mechanistic role in the action of hallucinogenic drugs (Burris *et al.*, 1991).

There is a significant correlation between the affinities of phenylalkylamine hallucinogens for 5-HT<sub>2C</sub> receptors and their potencies to evoke psychoactive effects in humans and to substitute in DOM-trained animals (Titeler *et al.*, 1988). Nevertheless, 5-HT<sub>2A</sub> and 5-HT<sub>2C</sub> receptors display parallel structure–affinity relationships for ligand binding (Nelson *et al.*, 1999), so it is possible that the observed correlation between 5-HT<sub>2C</sub> receptor affinity and hallucinogen potency merely reflects the relationship between 5-HT<sub>2A</sub> and 5-HT<sub>2C</sub> affinities. Importantly, for a series of structurally diverse 5-HT<sub>2</sub> antagonists, the rank order of potencies for blocking LSD-like stimulus effects (Fiorella *et al.*, 1995) and DOI-induced HTR (Schreiber *et al.*, 1995) does not parallel their 5-HT<sub>2C</sub> affinity. These findings strongly indicate that interactions with 5-HT<sub>2C</sub> receptors are not primarily responsible for mediating the behavioral effects of hallucinogens. Further, 5-HT<sub>2C/2B</sub> antagonists (SB 200,646A, SB 206,553, and SER-082) and the selective 5-HT<sub>2C</sub> antagonist SB 242,084 consistently fail to block the effects of hallucinogens in a variety of behavioral

paradigms (Schreiber *et al.*, 1994; Sipes and Geyer, 1995; Krebs-Thomson *et al.*, 1998; Wettstein *et al.*, 1999; Smith *et al.*, 1999; Ouagazzal *et al.*, 2001; Winter *et al.*, 2007). Although findings suggesting that 5-HT<sub>2C</sub> receptor interactions may contribute to or modify the effects of some hallucinogens have occasionally been reported (Smith *et al.*, 2003; Krebs-Thomson *et al.*, 1998, 2006), the vast majority of evidence demonstrates that the behavioral effects of these drugs are not dependent on the 5-HT<sub>2C</sub> receptor.

### 5-HT<sub>1A</sub> receptor

LSD and other indoleamine hallucinogens are agonists at 5-HT<sub>1A</sub> autoreceptors, and the indoleamines potently inhibit the firing of serotonergic neurons in the dorsal raphe nucleus (DRN) (Aghajanian *et al.*, 1968, 1970). Indoleamine hallucinogens also directly inhibit firing in many DRN target regions, but at low doses they preferentially inhibit DRN cells while leaving downstream neurons virtually unaffected (Haigler and Aghajanian, 1974; DeMontigny and Aghajanian, 1977). The finding that hallucinogens are more potent at presynaptic than postsynaptic sites led to the proposal that by depressing the activity of neurons in the DRN and thereby decreasing 5-HT outflow, hallucinogenic drugs remove the tonic inhibition of downstream neurons mediated by serotonin. Further research, however, identified several problems with this ‘presynaptic hypothesis’ of hallucinogen action. One of the most serious discrepancies was the finding that phenylalkylamine hallucinogens such as mescaline and DOM display negligible 5-HT<sub>1A</sub> binding affinity and do not consistently depress DRN firing (Haigler and Aghajanian, 1973; Penington and Reiffenstein, 1986). Furthermore, selective 5-HT<sub>1A</sub> agonists such as buspirone, ipsapirone and flesinoxan inhibit DRN cell firing but are not hallucinogenic.

The ability to inhibit DRN cell firing is clearly an epiphenomenon unrelated to hallucinogenesis. Nonetheless, the 5-HT<sub>1A</sub> agonist activity of indoleamines does appear to contribute to their behavioral effects. As was noted earlier, the effects of LSD and 5-MeO-DMT in the BPM are partially mediated by the 5-HT<sub>1A</sub> receptor. There is also considerable evidence that the 5-HT<sub>1A</sub> receptor plays a role in the discriminative stimulus effects of LSD and 5-MeO-DMT. LSD elicits intermediate levels of drug-lever selection in rats trained with the 5-HT<sub>1A</sub> agonist 8-OH-DPAT, and the 5-HT<sub>1A</sub> agonist ipsapirone elicits partial substitution in LSD-trained animals (Arnt, 1989). Likewise, the LSD stimulus completely generalizes to the mixed 5-HT<sub>1A</sub> agonist/ $\alpha_2$ -adrenoceptor antagonist yohimbine (Colpaert, 1984; Marona-Lewicka and Nichols, 1995). 8-OH-DPAT and ipsapirone produce full substitution

in animals trained with 5-MeO-DMT (Spencer *et al.*, 1987; Schreiber and DeVry, 1993; Winter *et al.*, 2000). In fact, it has been reported that WAY-100635 and the mixed 5-HT<sub>1</sub>/β-adrenergic antagonist pindolol are more effective than pirenperone and ketanserin at blocking stimulus control by 5-MeO-DMT, indicating that the 5-MeO-DMT discriminative stimulus involves a substantial 5-HT<sub>1A</sub> receptor-mediated component (Spencer *et al.*, 1987; Winter *et al.*, 2000). These observations are consistent with evidence that the behavioral response to 5-MeO-DMT in rats is predominantly mediated by the 5-HT<sub>1A</sub> receptor (Tricklebank *et al.*, 1985; Krebs-Thomson *et al.*, 2006).

There is also evidence that activation of the 5-HT<sub>1A</sub> receptor can inhibit 5-HT<sub>2A</sub> receptor-induced behavioral effects. 8-OH-DPAT pretreatment dose-dependently attenuates the head-twitch response to DOI in rats and mice (Arnt and Hyttel, 1989; Berendsen and Broekkamp, 1990; Darmani *et al.*, 1990), and the reciprocal hindleg body scratch induced by DOI in the gerbil (Eison and Wright, 1992). Furthermore, although both 8-OH-DPAT and DOI reduce locomotor activity in rats, there is an infra-additive interaction when the two drugs are co-administered, suggesting that they act as functional antagonists (Krebs-Thomson and Geyer, 1998).

### 5-HT<sub>5,6,7</sub> receptors

Indoleamine hallucinogens such as LSD, 5-MeO-DMT and psilocin bind with relatively high affinity to 5-HT<sub>5</sub>, 5-HT<sub>6</sub>, and 5-HT<sub>7</sub> receptors. Until recently, however, there were few pharmacological tools available to probe 5-HT<sub>5</sub>, 5-HT<sub>6</sub>, and 5-HT<sub>7</sub> sites, and therefore there has been no systematic investigation to determine whether these receptors contribute to the behavioral effects of the indoleamines. Experiments conducted in 5-HT<sub>5A</sub><sup>-/-</sup> knockout mice indicate that the ability of LSD to increase exploratory behavior is partially dependent on the 5-HT<sub>5A</sub> receptor (Grailhe *et al.*, 1999). It has been reported that the 5-HT<sub>6</sub> receptor is not involved in the LSD-induced decrease of PPI in rats (Ouagazzal *et al.*, 2001). Although interactions with 5-HT<sub>5</sub>, 5-HT<sub>6</sub>, and 5-HT<sub>7</sub> receptors may modulate the effects of the indoleamines, given the low affinity of the phenylalkylamines for these receptors it is unlikely that any of these sites are responsible for mediating the characteristic behavioral effects of hallucinogens.

### Dopamine receptors

Based on evident similarities between the symptoms of schizophrenia and those of the so-called 'model psychosis' induced by hallucinogenic drugs, and because dopamine

antagonists such as chlorpromazine and haloperidol have been used to counteract hallucinogen-induced psychotic episodes and panic reactions, it has been proposed that interactions with dopaminergic systems are involved in the mechanism of action of hallucinogens. It is now well established that indolealkylamine and phenylalkylamine hallucinogens lack appreciable affinity for dopamine receptors; consequently, it is unlikely that direct interactions with dopamine receptors are responsible for the behavioral effects of those agents. Conversely, like many other ergot alkaloids, LSD binds to D<sub>1</sub>, D<sub>2</sub>, D<sub>3</sub>, D<sub>4</sub> and D<sub>5</sub> receptors (Nichols *et al.*, 2002), and acts as a partial agonist at D<sub>1</sub> receptors (Watts *et al.*, 1995).

There is evidence that dopaminergic mechanisms play a role in the discriminative stimulus properties of LSD. Although the 5-HT<sub>2A</sub>/D<sub>2</sub> antagonist risperidone and the 5-HT<sub>2</sub> antagonist ritanserin bind to the 5-HT<sub>2A</sub> receptor with comparable affinities (Leysen, 1990), risperidone blocks LSD discrimination with 414 times the potency of ritanserin (Koek *et al.*, 1992). A 0.63-mg/kg dose of ritanserin produces full occupation of 5-HT<sub>2A</sub> sites in rats, yet fails to attenuate the LSD stimulus; it is not until a much higher dose of 40 mg/kg is administered, where ritanserin is capable of interacting with catecholamine receptors, that it can completely antagonize the LSD cue (Meert *et al.*, 1990; Koek *et al.*, 1992). Conversely, risperidone and ritanserin antagonize the DOM cue with similar potencies (ED<sub>50</sub> values of 0.024 mg/kg and 0.15 mg/kg, respectively; Meert, 1996). Taken together, these findings argue that both 5-HT<sub>2A</sub> and D<sub>2</sub> receptor interactions contribute to the interoceptive state governing LSD discrimination, whereas DOM discrimination involves only the 5-HT<sub>2A</sub> receptor. In support of this conclusion, it was observed that the ED<sub>50</sub> of ritanserin for blocking LSD stimulus control is reduced 53-fold when administered in combination with 0.04 mg/kg haloperidol (Meert and Awouters, 1991). It has also recently been reported that the dopaminergic component of the LSD discriminative stimulus is time-dependent (Marona-Lewicka *et al.*, 2005). Studies that have trained rats to discriminate LSD have typically used pretreatment times of 15–30 minutes, and have consistently shown that the LSD cue is blocked by 5-HT<sub>2A</sub> antagonists. When a longer pretreatment time of 90 minutes is used, however, the resulting LSD cue is apparently mediated by D<sub>4</sub> receptors rather than by 5-HT<sub>2A</sub> receptors (Marona-Lewicka *et al.*, 2008).

### Chemistry and structure–activity relationships

As discussed above, the serotonin 5-HT<sub>2A</sub> receptor is now generally considered to be the key target for hallucinogens (Nichols, 2004). As such, one might therefore expect the

**Figure 1** The structures of the natural transmitter serotonin and the tryptamine-type hallucinogens psilocin, DMT and LSD.

**Figure 2** The structures of mescaline, the prototypical phenethylamine hallucinogen, and general formulas for synthetic substituted hallucinogenic phenethylamines and 'amphetamines'. For the alpha-substituted amphetamines, the stereoisomer with the *R*-(−)- absolute configuration (shown) is more potent.

hallucinogens to bear some structural resemblance to serotonin. This relationship is quite evident with the simple tryptamines and with the tetracyclic ergoline LSD. Indeed, it was the recognition that the tryptamine fragment within the structure of LSD also was the core feature of serotonin itself that first led to the realization that serotonin might play a role in behavior. A comparison of the structures of serotonin and the hallucinogens DMT, 5-methoxytryptamine, psilocin and LSD is presented in Figure 1. It is not difficult to understand why all of these structures interact with serotonin receptors, because of their close structural resemblance. Although LSD is a more complex molecule, the tryptamine core fragment is still readily apparent.

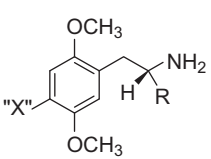

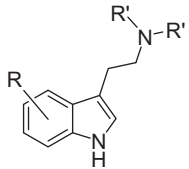

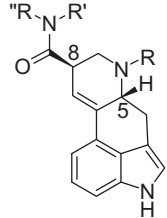

What is less clear, though, is how the phenethylamine type hallucinogens (Figure 2) interact with serotonin receptors. The only apparent similarity is a basic nitrogen atom two carbon atoms removed from an aromatic system. Recent mutagenesis studies of the 5-HT<sub>2A</sub> receptor have, however, begun to reveal the basis for the requirement of certain structural features of the phenethylamines to interact with the receptor (Figure 3).

Studies of the mutant S239A 5-HT<sub>2A</sub> receptor have demonstrated that it is this serine residue, in transmembrane helix 5, that likely hydrogen bonds to the 5-hydroxy group of serotonin, as well as to the 5-methoxy group of

the 2,5-dimethoxy-substituted phenethylamines (Braden and Nichols, 2007). Figure 4 suggests possible binding modes for the 2,5-dimethoxy-substituted phenethylamines and the tryptamines, based on those studies.

This view could explain why a primary amine is most potent for the phenethylamines, with *N*-alkyl or *N,N*-dialkyl derivatives being essentially inert, whereas tertiary amines are potent in the tryptamine series. That is, one might envision that the binding site must 'shrink' or compress to accommodate a phenethylamine. That is most readily achieved by rotation of the side-chain of Asp155 in transmembrane helix 3. If this aspartate engages the amino group in an 'end on' conformation for the phenethylamines, it might be speculated that *N*-alkyl groups would hinder that interaction. By contrast, aspartate residue could engage the amino group of the tryptamines through an approach more perpendicular to the plane of the molecule. In this event, *N*-alkyl groups would be expected to have less of an effect on the ligand interaction. The argument can likely be extended to understand the binding of LSD, because its structure is so rigid that interaction of Asp155 with the protonated electron pair of the amino group can only occur through an 'axial' approach to the amine moiety.

Substitution of an alpha-methyl group on the phenethylamine side-chain gives more potent compounds.

**Figure 3** Summary of structure–activity relationships (SAR) for classes of hallucinogens.

There are at least three possible explanations, all of which probably make some contribution. First of all, the alpha methyl will retard metabolic deamination, giving better oral availability and increased *in vivo* stability. Second, the alpha methyl adds significant hydrophobicity, leading to better brain penetration. Finally, *R*-alpha-methyl-substituted phenethylamines generally are more efficacious in activating second messenger systems than their non-alkylated congeners (Parrish *et al.*, 2005). At least for the phenethylamines (‘amphetamines’) the alpha methyl group enhances the intrinsic activity, possibly through an interaction with a critical phenylalanine residue in trans-membrane helix 6. The steric limitation in this region is very strict, however, as any larger alkyl group, even an ethyl, destroys activity.

Interestingly, the stereochemistry is reversed for alpha-substituted tryptamines. One may speculate that the two classes of ligands bind in such a way as to project the alpha-methyl groups into the same general region of the receptor, but there are no data to support that supposition. The different lengths of the ligands also may be a key here. For example, Figure 4 illustrates *S*-(+)-alpha-methyl serotonin and the more potent *R*-(-)- isomer of a rigid phenethylamine. In these orientations, representing potential receptor-bound conformations, the distance from the side-chain amino nitrogen to the 5-oxygen atom is 6.1 and 6.6 Ångstroms for the phenethylamine and the tryptamine, respectively.

Incorporating the 2- and 5-methoxy groups into furan or dihydrofuran rings gives compounds that are more potent, but, more importantly, establishes the binding orientations for the two methoxys. Simulating docking experiments suggest that the 2-methoxy group of the phenethylamines engages Ser159 through a hydrogen bond (Braden, 2007). Attempts to test that hypothesis with the S159A mutant receptor gave a protein that had such drastically reduced function that it was not possible to examine the effect of the presence or absence of the 2-methoxy of the ligand.

Although substitution at the 6-indole position of the tryptamines renders them inactive (Blair *et al.*, 2000), substituting the phenethylamines at the 4-position is essential to provide good activity. Again, the different sizes of the phenethylamines and tryptamines are likely at the heart of this observation. Simulating docking experiments suggest that the 4-substituent of the phenethylamines projects into a hydrophobic area of the receptor between trans-membrane helices 3, 4 and 5 created by residues Phe234, Ile206 and Val156. It may be that the larger indole ring of the tryptamines projects into this space, and additional bulk attached to the ligand in this region creates too large a steric footprint for the receptor to accommodate.

3,4,5-substituted phenethylamines (e.g., mescaline) do not bind in the same way as the 2,4,5-substituted compounds, because site specific mutations of the receptor lead to different effects on 2,4,5- vs the 3,4,5- substituted

**Figure 4** Comparison of the *R*(-)- isomer of a potent difuranobenzene phenethylamine type hallucinogen (A) with *S*(+)-α-methylserotonin (B). Although the stereochemistry at the carbon bearing the alpha-methyl is reversed for the phenethylamines and the tryptamines, the lengths of the ligands, differing by about 0.5 Ångstroms (C), could be the underlying reason for this reversal. The bicyclic aromatic indole system of the tryptamines is longer than the phenyl ring of the phenethylamines, and thus when the side-chain is extended, the tryptamines will occupy a larger space in the receptor. Because the receptor evolved to accept serotonin, a tryptamine, the perspective must be one that the phenethylamines somehow adapt themselves to a binding site that prefers tryptamines. To see the full color version of this figure please refer to the color plate at the back of the book. Copies produced via our print on demand service do not contain color plates. If your copy does not have the color plate, please go to this website to view the figure in color [www.elsevierdirect.com/companions/9780123746344](http://www.elsevierdirect.com/companions/9780123746344)

compounds (Braden, 2007). Nevertheless, a hydrophobic 4-alkoxy substituent in the 3,4,5-substituted compounds also gives highest activity in this series (Nichols and Dyer, 1977; Shulgin and Shulgin, 1991), and simulated docking into homology models of the receptor suggests that this substituent projects into the same receptor space as the 4-substituent in the 2,4,5-substituted series.

The rigid nature of LSD limits its conformational flexibility upon binding. Mutagenesis studies suggest that the indole NH hydrogen bonds to Ser242 in transmembrane helix 5 (Braden and Nichols, 2007), and the electron pair on the amine nitrogen is probably directed in an axial orientation toward the conserved aspartate in helix 3.

Very little structural modification can be tolerated by ergolines related to LSD. The stereochemistry at both the

5- and 8-positions must be of the *R* configuration, shown in Figures 1 and 4. Inversion at C(8) affords iso-LSD, which is inactive. Halogenation at the 2-indole of LSD position affords antagonists such as BOL that lack hallucinogenic activity. Although N(1)-acetylation leads to an active compound, this molecule is actually a prodrug and the *N*-acetyl is readily cleaved *in vivo* to afford LSD itself.

The bulky diethylamide moiety is relatively limited in its conformational flexibility (Pfaff *et al.*, 1994), and virtually any modification of the diethylamide gives about an order of magnitude decrease in potency. Constraining the diethylamide into a 2,4-dimethylazetidide, however, did lead to a compound with potency comparable to LSD in the rat drug discrimination paradigm (Nichols *et al.*, 2002). The stereoisomer with the 2*S*,4*S*-absolute configuration in the azetidide ring gave the most potent lysergamide, demonstrating that the receptor binding site for the amide moiety of LSD is stereospecific, and uniquely complementary to the diethylamide function. Simulating docking experiments show that the diethylamide moiety is forced to project toward extracellular loop 2 (EL2), suggesting that EL2 may play an important role in LSD binding in the 5-HT<sub>2A</sub> receptor, as is now known for many other GPCRs.

The only structural modification known to enhance activity is homologation of the N(6)-alkyl group. That is, replacing the N(6)-methyl with an ethyl, *n*-propyl, or *n*-allyl gives compounds slightly more active than LSD in rat behavioral models (Hoffman and Nichols, 1985).

### Receptors mediating the behavioral effects of MDMA in animals

MDMA (Figure 5) is a potent monoamine-releasing drug (Johnson *et al.*, 1986; Nichols *et al.*, 1986; Baumann *et al.*, 2008). Neurochemical studies have demonstrated that MDMA binds to monoamine transporters, is a substrate for the transporters, and increases the non-exocytotic release of serotonin, dopamine and norepinephrine. MDMA also displays moderate affinity for 5-HT<sub>2A</sub> receptors (Lyon *et al.*, 1986).

As contrasted with the hallucinogenic amphetamines, where the stereochemistry at the alpha side-chain carbon bearing the methyl group is *R*, the stereochemistry in the side-chain of the more potent enantiomer of MDMA is *S*, which corresponds to that of the psychostimulant amphetamines. The alpha-methyl can be homologated to an ethyl

**Figure 5** The structure of 3,4-methylenedioxyamphetamine (MDMA).

group with retention of activity, and the *N*-methyl that is present in MDMA is not tolerated in the hallucinogenic amphetamines. These structural features are strong evidence that MDMA is not simply a hallucinogenic amphetamine, but belongs to a distinct class of psychoactive agents called entactogens (Nichols *et al.*, 1986; Nichols and Oberlender, 1990).

### Drug discrimination

Rats can be trained to discriminate MDMA from vehicle (Schechter, 1987; Oberlender and Nichols, 1988). The MDMA stimulus completely generalizes to drugs that produce MDMA-like subjective effects in humans, including *N*-ethyl-3,4-methylenedioxyamphetamine (MDE) and 1-(1,3-benzodioxol-5-yl)-*N*-methylbutan-2-amine (MBDB) (Oberlender and Nichols, 1988; Glennon and Misenheimer, 1989). By contrast, the MDMA stimulus does not generalize to LSD or DOM (Oberlender and Nichols, 1988), and MDMA does not substitute in rats trained with LSD (Nichols *et al.*, 1986). These findings demonstrate that the stimulus cue evoked by MDMA is clearly distinct from that produced by hallucinogens.

The neurochemical basis for the discriminative stimulus effects of MDMA is complex, and is incompletely characterized. The fact that MDMA generalizes to the indirect 5-HT agonists norfenfluramine (Schechter, 1988) and *p*-methoxyamphetamine (Nichols and Oberlender, 1989) indicates that 5-HT release plays a role in the stimulus effects of MDMA. The finding that the 5-HT antagonist pizotyline completely blocks MDMA discrimination (Young *et al.*, 2005) is consistent with 5-HT receptor mediation of MDMA stimulus control, but the identity of the specific 5-HT receptor subtype(s) involved remains to be elucidated. There is some disagreement in the literature regarding the extent to which the MDMA stimulus generalizes to the selective 5-HT<sub>1A</sub> receptor agonist 8-OH-DPAT (Schechter, 1988; Glennon and Young, 2000). Nonetheless, the finding that the 5-HT<sub>1A</sub> antagonist NAN-190 fails to block MDMA discrimination completely (Glennon *et al.*, 1992) suggests that 5-HT<sub>1A</sub> receptors do not play a primary role in MDMA discrimination. Although the 5-HT<sub>2</sub> antagonists ketanserin and pirenperone partially attenuate MDMA stimulus control (Glennon *et al.*, 1992), it is unlikely that 5-HT<sub>2</sub> receptor subtypes contribute appreciably to the MDMA discriminative stimulus because DOM does not substitute in animals trained with MDMA. In light of the structural similarities between MDMA and amphetamine, and given the fact that both drugs increase dopamine release, it does not seem unreasonable to assume that there may be a psychostimulant-like

component to the MDMA interoceptive stimulus. Indeed, the MDMA stimulus completely generalizes to *S*-(+)-amphetamine (AMPH) and cocaine (Oberlender and Nichols, 1988; Khorana *et al.*, 2004). At the same time, however, MDMA does not substitute in animals trained with either AMPH or cocaine (Oberlender and Nichols, 1988; Khorana *et al.*, 2004). The asymmetric generalization between MDMA and AMPH indicates that MDMA produces a compound stimulus, with one element of the MDMA cue being AMPH-like. It has been reported that AMPH does not substitute in animals trained with (+)-MBDB (Oberlender and Nichols, 1990), a compound that produces symmetrical cross-generalization with MDMA. (+)-MBDB increases 5-HT release but has little effect on dopamine release (Johnson *et al.*, 1986). Taken together, these findings indicate that the most salient component of the MDMA stimulus (i.e., the (+)-MBDB-like effect) is transduced via 5-HT release, with dopamine release mediating a secondary nonessential AMPH-like component. The fact that dopamine antagonists have little or no effect on MDMA discrimination (Schechter, 1988; Glennon *et al.*, 1992) provides further support for the conclusion that dopamine release is not essential for the induction of MDMA stimulus control.

### Locomotor activity

Administration of MDMA to rats and mice produces an increase in locomotor activity that is accompanied by thigmotaxis (Gold *et al.*, 1988). MDMA does not induce hyperactivity in 5-HT transporter (SERT)<sup>-/-</sup> knockout mice (Bengel *et al.*, 1998) or in rats pretreated with 5-HT uptake inhibitors (Callaway *et al.*, 1990), indicating that the effect of MDMA is dependent on carrier-mediated release of 5-HT. There is considerable evidence that 5-HT<sub>1B</sub> and 5-HT<sub>2A</sub> receptors mediate the locomotor response to MDMA (McCreary *et al.*, 1999; Scarce-Levie *et al.*, 1999; Fletcher *et al.*, 2002; Ball and Rebec, 2005). However, there is also a dopaminergic component to the MDMA locomotor response (Gold *et al.*, 1989; Baumann *et al.*, 2008). MDMA is a potent releaser of dopamine, and there is a significant correlation between MDMA-induced hyperlocomotion and extracellular dopamine levels in the nucleus accumbens (Baumann *et al.*, 2008). Antagonist and gene deletion studies have confirmed that MDMA acts partially via D<sub>1</sub> and D<sub>2</sub> receptors to increase locomotor activity (Ball *et al.*, 2003; Bubar *et al.*, 2004; Risbrough *et al.*, 2006). Recently, it was reported that the selective  $\alpha_1$ -adrenoceptor antagonist prazosin can block the locomotor response to MDMA (Selken and Nichols, 2007), demonstrating that MDMA-induced norepinephrine release also contributes to the locomotor effects of the drug.

*Prepulse inhibition of startle*

PPI is attenuated by MDMA and MDE in rats and mice (Mansbach *et al.*, 1989; Dulawa and Geyer, 1996; Kehne *et al.*, 1996). Padich *et al.* (1996) have shown that the ability of MDMA to disrupt PPI is completely blocked by M100907, indicating 5-HT<sub>2A</sub> receptor involvement. Pretreatment with haloperidol did not block the effect of MDMA on PPI. Several other indirect 5-HT agonists, including *p*-chloroamphetamine and fenfluramine, have also been shown to disrupt PPI (Kehne *et al.*, 1996; Padich *et al.*, 1996). As was found with MDMA, the effect of fenfluramine on PPI is dependent on 5-HT<sub>2A</sub> receptors (Padich *et al.*, 1996).

**Clinical studies of hallucinogens in humans***Assessment of hallucinogen-induced altered states of consciousness*

The 'Altered States of Consciousness' (APZ) rating scale is a self-administered questionnaire that was developed by Dittrich to assess alterations of consciousness (Dittrich, 1998). Numerous clinical trials have confirmed that the APZ rating scale is sensitive to the effects of hallucinogens, including DMT, psilocybin, *ayahuasca* and mescaline (Hermle *et al.*, 1992; Vollenweider *et al.*, 1997; Dittrich, 1998; Vollenweider *et al.*, 1998a; Gouzoulis-Mayfrank *et al.*, 1999, 2005; Riba *et al.*, 2002; Hasler *et al.*, 2004; Griffiths *et al.*, 2006). Dittrich has proposed that the subjective effects of hallucinogens can be divided into three major dimensions: (1) 'Oceanic Boundlessness' (OB), (2) 'Anxious Ego Dissolution' (AED), and (3) 'Visionary Restructuralization' (VR). The OB dimension is similar to classical mystical experiences, and involves a pleasant state of depersonalization and derealization. The AED dimension includes dysphoric effects such as anxiety, thought disorder, delusions, fear of losing control, and ego disintegration. The VR dimension includes perceptual phenomena such as visual hallucinations and illusions, synesthesia, and changes in the meaning of percepts. Studies using an updated version of the APZ, the 5D-ASC, have shown that psilocybin also increases scores in a dimension known as 'Reduction of Vigilance' (RV), which includes measures of drowsiness, cognitive impairment and decreased alertness (Hasler *et al.*, 2004; Carter *et al.*, 2007; Vollenweider *et al.*, 2007). Psilocybin can produce auditory effects, but only when high doses are administered (Hasler *et al.*, 2004). An [<sup>18</sup>F]FDG PET study has demonstrated that psilocybin increases cerebral glucose metabolic activity in the prefrontal cortex, anterior cingulate, temporomedial cortex and putamen, and the increased metabolic rate within those regions was

found to be significantly correlated with subjective effects in the OB, VUS and AED dimensions (Vollenweider *et al.*, 1997).

*Mechanism of hallucinogen effects in humans*

One focus of investigation has been to determine how interactions with specific neurotransmitter systems contribute to the effects of hallucinogens in humans. A few early studies addressed this issue by attempting to block the effects of LSD with serotonin, dopamine and nor-epinephrine receptor antagonists (Isbell and Logan, 1957; Isbell *et al.*, 1959). Unfortunately, due to the fact that high-affinity receptor-selective antagonists were not available at the time, those studies failed to link the action of hallucinogens to any particular transmitter system. The recent resumption of human hallucinogen studies has coincided with the development of selective antagonist ligands, and these compounds have been used to assess how interactions with serotonergic and dopaminergic receptors contribute to the effects of hallucinogens.

*DMT*

Meltzer and colleagues (Tueting *et al.*, 1992) examined whether the moderately selective 5-HT<sub>2A/2C</sub> antagonist cyproheptadine and the D<sub>2</sub> antagonist haloperidol could block the psychological effects induced by DMT in normal human volunteers. Neither drug effectively blocked the effects of DMT, and in some subjects the effects of DMT were actually intensified by pretreatment with cyproheptadine. The finding that cyproheptadine intensified the effects of DMT is intriguing in light of reports that high doses of cyproheptadine produce LSD-like behavioral effects in rats (Colpaert *et al.*, 1982). Nonetheless, it is not clear that the dose of cyproheptadine used in the study (4mg, p.o.) produces significant occupation of 5-HT<sub>2</sub> sites. The mixed 5-HT<sub>1A/1B</sub>/β-adrenergic antagonist pindolol has been used to assess the involvement of 5-HT<sub>1A</sub> receptors in the response to DMT (Strassman, 1996). Pretreatment with pindolol markedly intensified the subjective effects of DMT, suggesting that activation of 5-HT<sub>1A</sub> receptors by DMT acts to attenuate the hallucinogenic effects of the drug.

*Psilocybin*

As part of a series of studies of the effects of psilocybin in human volunteers, Vollenweider and colleagues have assessed the effect of pretreatment with the 5-HT<sub>2A</sub> antagonist ketanserin, the mixed D<sub>2</sub>/5-HT<sub>2A</sub> antagonist

risperidone, and haloperidol. The effects of psilocybin on the OB, AED and VR dimensions of the APZ were reduced by pretreatment with 20 mg ketanserin (p.o.) and almost completely blocked by pretreatment with either 40 or 50 mg ketanserin (Vollenweider *et al.*, 1998a; Carter *et al.*, 2007). Likewise, pretreatment with 0.5 and 1.0 mg risperidone (p.o.) produced partial and complete blockade, respectively, of the subjective effects of psilocybin (Vollenweider *et al.*, 1998a). Conversely, haloperidol was much less effective, producing only partial blockade of psilocybin effects in the OB dimension, while actually increasing scores in the AED dimension. Taken together, these findings confirm that the hallucinogenic effects of psilocybin in humans are primarily mediated by actions at the 5-HT<sub>2A</sub> receptor, with D<sub>2</sub> receptor interactions playing only a minor role.

### ***Effect of MDMA in humans***

The effects of MDMA and the related homolog MDE in humans have been examined in clinical trials. Treatment with either MDMA or MDE produced effects such as heightened mood, a sense of relaxation, empathy, feelings of closeness to others, stimulation, and minor perceptual and cognitive disturbances (Hermle *et al.*, 1993; Vollenweider *et al.*, 1998b). Although MDMA and MDE did produce some psychostimulant- and hallucinogen-like effects, a double-blind placebo controlled study confirmed that the subjective effects of the entactogens are distinct from those of *S*-(+)-methamphetamine and psilocybin (Gouzoulis-Mayfrank *et al.*, 1999). The latter study also found that the effects of MDE on core APZ dimensions were intermediate between those of psilocybin and *S*-(+)-methamphetamine, providing additional confirmation that differences exist between the subjective effects of these three drugs. Interestingly, in trials comparing the two enantiomers of MDE, the *S*-enantiomer produced entactogenic effects whereas the *R*-enantiomer elicited mainly dysphoric effects (Spitzer *et al.*, 2001). This finding distinguishes MDE from phenylisopropylamine hallucinogens such as DOM, DOB and DOET, for which the *R*-enantiomer is the more active stereoisomer (Shulgin, 1973; Shulgin *et al.*, 1971; Snyder *et al.*, 1974).

### ***Mechanism of MDMA effect in humans***

Pretreatment with the selective 5-HT reuptake inhibitor citalopram significantly attenuated most of the subjective effects of MDMA, consistent with the proposed involvement of carrier-mediated 5-HT release in the effects of MDMA (Liechti *et al.*, 2000a; see also this volume).

Citalopram also blocked the cardiovascular response to MDMA (Liechti and Vollenweider, 2000a) and inhibited the effect of MDMA on PPI (Liechti *et al.*, 2001). Pretreatment with ketanserin produced some attenuation of the subjective effects of MDMA (Liechti *et al.*, 2000b). However, the most significant reduction of MDMA effects by ketanserin occurred in the VR dimension of the APZ, indicating that 5-HT<sub>2A</sub> receptors are responsible for the effects of MDMA on perception. Haloperidol pretreatment reduced the euphoric effects of MDMA but increased MDMA-induced dysphoria (i.e., scores in the AED dimension) (Liechti and Vollenweider, 2000b). Neither ketanserin nor haloperidol blocked the cardiovascular effects of MDMA (Liechti and Vollenweider, 2000b; Liechti *et al.*, 2000b) or the ability of the drug to increase PPI (Liechti *et al.*, 2001). Pretreatment with pindolol did not substantially alter either the subjective effects of MDMA or its effect on measures of cognitive performance (Hasler *et al.*, 2008). The fact that interactions with the 5-HT<sub>1A</sub> receptor do not appear to contribute to the effects of MDMA in humans stands in contrast to the preclinical evidence in rodents indicating that the 5-HT<sub>1A</sub> receptor plays a role in the behavioral effects of MDMA (Millan and Colpaert, 1991; Glennon and Young, 2000; Morley *et al.*, 2005). In summary, these findings demonstrate that the subjective effects of MDMA are largely attributable to increases in 5-HT release, with D<sub>2</sub> and 5-HT<sub>2A</sub> receptor stimulation contributing to the mood-elevating and hallucinogen-like perceptual effects, respectively, of MDMA.

### **Summary**

Over the past three decades, substantial progress has been made toward understanding how hallucinogens exert their complex behavioral effects. It is now well established that serotonergic hallucinogens bind to the 5-HT<sub>2A</sub> receptor, and a large body of preclinical evidence demonstrates that the behavioral effects of the hallucinogens are primarily mediated by interactions with the 5-HT<sub>2A</sub> receptor. Importantly, due to the recent resumption of human clinical studies with hallucinogens, it has been possible to confirm that the 5-HT<sub>2A</sub> receptor also plays a primary role in the effects of hallucinogens in humans.

The drug MDMA has been a topic of intense study in recent years. Although there is some overlap between the effects of entactogens and hallucinogens, there are considerable pharmacological differences between these two classes of compounds. The effects of MDMA are largely attributable to increases in the release of serotonin, a fact that has been confirmed in clinical studies with human subjects. Studies of MDMA and the hallucinogens have

proven to be extremely informative regarding the pharmacology of these agents. These investigations have also provided insight into how the central serotonergic system acts to modulate behavior.

Most recently, in a study where psilocybin was administered to normal human volunteers, effects were characterized by a majority of the subjects as among the most meaningful experiences of their lives. Positive effects on mood and behavior were manifest, and at 14-month follow-up were still significantly above values prior to the study (Griffiths *et al.*, 2006, 2008). Several clinical studies are now under way to determine whether these effects may provide value in reduction of stress and anxiety in the treatment of cancer patients. It is anticipated that future investigations with hallucinogens, especially research conducted in humans, will yield additional insight into the psychopharmacology of hallucinogens and the behavioral influence of serotonin.

# The Role of Serotonin in Cortical Development: Implications for Autism Spectrum Disorder

Christine F. Hohmann<sup>\*,1</sup> and Mary E. Blue<sup>2</sup>

<sup>1</sup>*Department of Biology, Morgan State University, Baltimore, Maryland*

<sup>2</sup>*Department of Neurology and Neuroscience, Johns Hopkins University School of Medicine, Hugo W. Moser Research Institute at Kennedy Krieger, Neuroscience Laboratory, Kennedy Krieger Institute, Baltimore, Maryland*

**Abstract:** This chapter provides a review of basic research as well as clinical literature in support of the idea that altered serotonergic homeostasis is prominently involved in the pathogenesis of Autism Spectrum Disorder (ASD). Animal models of cortical serotonergic effects in development and plasticity are reviewed and juxtaposed to neuropathological and clinical findings in ASD. Based on the emerging conceptualization of ASD as a developmental disorder of cortical connectivity, we present a hypothesis about the role of serotonin in altered cortical network formation, as a substrate for altered cognitive function. Investigations into the role of serotonin in immune regulation, and particularly neuroimmune regulation, support a role for serotonin in a variety of homeostatic functions that may be impaired in ASD and can contribute to altered brain development and function. A unified hypothesis such as proposed here could provide an avenue towards early identification of biomarkers as well as therapeutic strategies. We hope to provide an impetus for new investigations into a ‘serotonergic hypothesis’ for ASD.

**Keywords:** serotonin, cerebral cortex, development and plasticity, autism spectrum disorder, neuroinflammation, cytokines, BDNF.

## Introduction

Attention on serotonin as modulator of cortical development and plasticity has come relatively late compared to research on the role of other afferent neuromodulator systems such as norepinephrine, dopamine and acetylcholine. In the mid-1990s, when Hohmann co-authored a review on neuromodulatory influences in cortical development, little direct evidence was available for serotonergic effects during critical periods of cortical development (Berger-Sweeney and Hohmann, 1997). This has dramatically changed in the decade since. Such interest likely has been precipitated by the increasing awareness of serotonergic involvement in a spectrum of mental health disorders with developmental origins and the rising prominence of serotonergically acting drugs in the treatment of mental health disorders (Stokes and Holtz, 1997; Murrin *et al.*, 2007; Thase and Denko, 2008). This, in turn, has led to rising concerns about the potential effects of such drug

treatments on the immature nervous system (Bonati and Clavenna, 2005; Gentile, 2007).

Our goal in this chapter is to present an overview of the experimental literature concerning serotonergic influences on the development of the cerebral cortical structure and, to a lesser extent, function within the context of serotonin involvement in the pathologies of Autism Spectrum Disorder [ASD]. We will largely concentrate on the rat/mouse somatosensory cortex and rat and cat visual cortex as model systems to illustrate current thinking concerning the role of 5-HT in the modulation of cortical development and plasticity. These two different paradigms, long used to study developmental plasticity in the cortex, are often contrasted in terms of the established contributions of synaptic activity on thalamocortical afferent pattern formation. It is generally presumed that the development of visual connections in cortex is more fundamentally under the control of patterned synaptic activity and that the somatosensory cortex is more strictly controlled by genetic information (Rebsam *et al.*, 2005). Both structures illustrate the importance of patterned sensory input on structural and functional development of the neocortex, and both

<sup>\*</sup>Corresponding author  
E-mail: christine.hohmann@morgan.edu

paradigms do have a 'critical period' for the proper development of functional sensory maps.

Knowing that other authors in this volume are likely to give some detail to general serotonergic effects in morphogenesis as well as to cognitive social and emotional behavioral consequences of altered serotonergic innervation in maturity, we will discuss behavioral effects only to the extent that they are specific to developmental serotonergic manipulations and differ from what is seen in the mature nervous system. Such behavioral studies will serve as a bridge to understanding the potential relevance of serotonin in the etiology of ASD, a disorder with early developmental onset. We will review the clinical evidence that points towards a developmental serotonergic imbalance in ASD along with the neuropathology that supports a serotonergic role, based on insights from the experimental literature. We will conclude by presenting a model for the role of 5-HT in the pathogenesis of ASD, and discuss this within the emerging conceptual framework of understanding that ASD is a disorder of neural network development, particularly in the cerebral cortex. There are many avenues, genetic and environmental, that can lead to altered serotonergic innervation during brain development, and, depending on the time that the innervation is disrupted, different endophenotypes might emerge and thus account for the spectrum of behavioral and neurobiological sequelae in ASD and, beyond that, other mental health disorders.

## Serotonin in cortical development

### *Development of the cortical serotonergic innervation*

In the mammalian cerebral cortex, serotonergic fibers typically appear perinatally and their maturation, as well as the maturation of their postsynaptic receptors, brackets the period of maximal developmental plasticity (Goldman-Rakic and Brown, 1982; Jonsson and Kasamatsu, 1983; Foote and Morrison, 1987; Gu *et al.*, 1990; Dyck and Cynader, 1993; Dori *et al.*, 1998; Harper and Wallace, 1995). In rat and mouse, 5-HT immunoreactive fibers enter the cortex at approximately embryonic days 18–19 and do not reach adult distribution patterns until 3–4 weeks postnatally (Lidov and Molliver, 1982; D'Amato *et al.*, 1987; Dori *et al.*, 1998; Janusonis *et al.*, 2004). Serotonin immunoreactive fibers from the medial forebrain bundle appear first in frontal cortical areas, and thereafter spread across parietal and occipital areas. Studies by Janusonis and colleagues suggest that serotonergic afferents first contact Cajal-Retzius neurons in the marginal zone, prior to birth, before entering the cortical plate (Janusonis *et al.*, 2004). The subsequent

cortical innervation pattern does not necessarily represent a gradual increase of fiber density or transmitter levels. 5-HT immunoreactivity in rat cortex is distributed in dense patches in sensory areas during the first postnatal week. After postnatal day 10 (P10) the patches of 5-HT immunoreactivity are no longer apparent, but the density of 5-HT axons gradually increases until an adult pattern is present at approximately 4 weeks of age (D'Amato *et al.*, 1987). Using electronmicroscopy, Dinopoulos and colleagues have observed transient accumulation of serotonin synapses during the most plastic period of development in rat visual and somatosensory cortex (Dinopoulos *et al.*, 1997). Rodent somatosensory cortex also displays a transient, patchy appearance when labeled with antibodies against the serotonin transporter (SERT) (Fujimiya *et al.*, 1986), and these transient immunoreactive patches are associated with clusters of thalamocortical afferents in their cortical targets, the barrel field (Blue *et al.*, 1991; Bruning and Liangos, 1997; Hansson *et al.*, 1998; Boylan *et al.*, 2000a). Serotonergic receptors (5-HT<sub>2A</sub>) also are transiently over-expressed in layer IV of barrel-field cortex (Mansour-Robaey *et al.*, 1998). Our early studies of monoamine levels in cortex, during the first few postnatal weeks, confirmed a peak of 5-HT and its metabolites within the first 5 days after birth, which is followed by a more gradual incline over the next 2 weeks (Hohmann *et al.*, 1988). We have since observed that the early postnatal peak is present in male mice but not apparent in female mice (Connell *et al.*, 2004). Different studies have confirmed, to date, that thalamocortical afferents actively sequester serotonin during this critical period of synaptic maturation in sensory cortical areas (Bennett-Clarke *et al.*, 1991; Bruning and Liangos, 1997). These data strongly suggest a role for the serotonergic innervation in the formation and perhaps plasticity of thalamocortical sensory afferent connections. We will further discuss the implication of these findings below.

Data from non-rodents suggest that a transient peak in serotonergic neurotransmission, associated with the development of thalamocortical afferent connections, may be a universal feature of mammalian cortical development (Murrin *et al.*, 2007). In cat visual cortex, a patchy distribution of 5-HT receptors has been reported in association with thalamic input columns, and most receptors have their peak expression during the 'critical period' of development (Dyck and Cynader, 1993; Kojic *et al.*, 2000). Receptors (particularly 5-HT<sub>2A</sub> receptors) in cat as well as rat visual and auditory cortex are increased several-fold during the first postnatal month compared to adult levels (Jonsson and Kasamatsu, 1983; Dyck and Cynader, 1993; Basura *et al.*, 2008). Similar observations have been made for 5-HT<sub>1</sub> and 5-HT<sub>2</sub> receptor binding autoradiography in prefrontal, somatosensory and visual cortex of rhesus

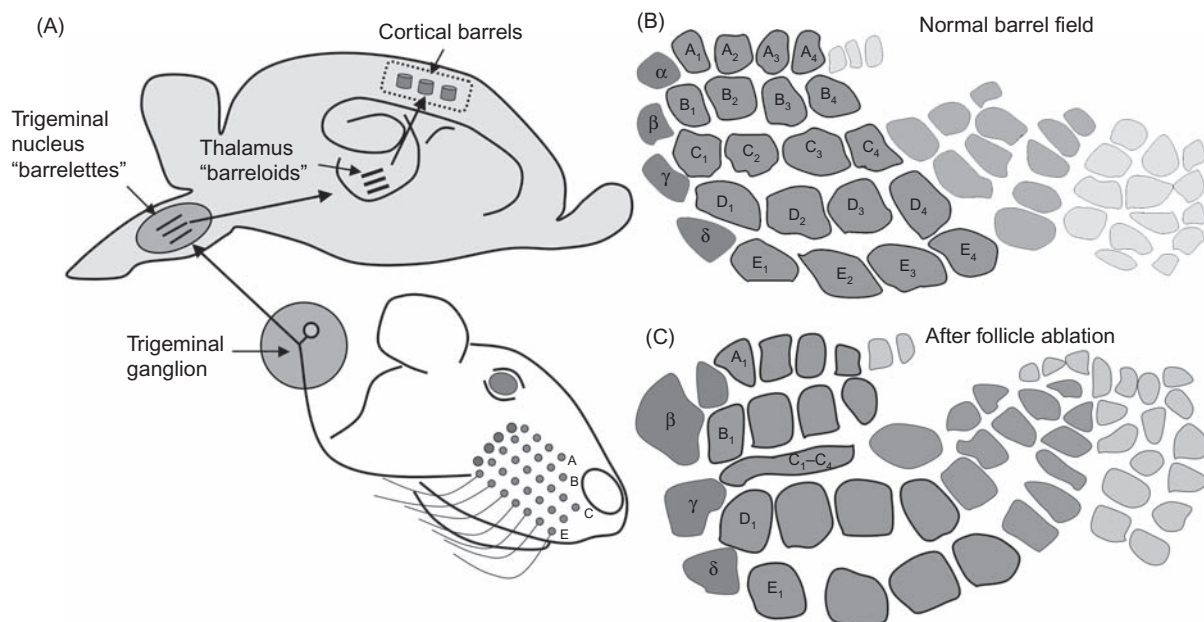

monkeys, where levels at 2 months of age were twice that in the adult (Lidow and Rakic, 1992). In kittens, an early peak of adult 5-HT levels is seen between 3 and 5 weeks postnatally, followed by a decline in levels and then a gradual recovery (Jonsson and Kasamatsu, 1983). High 5-HT and metabolite levels were also recently reported for rodent auditory cortex during the second postnatal week (Basura *et al.*, 2008). Last but not least, studies by Diane Chugani's laboratory, using imaging approaches, show a transient elevation of cortical serotonergic synthesis during the pre-school years in humans (Chugani *et al.*, 1999). These recent studies were preceded by earlier findings that serotonin receptor binding in human brain tissue increases postnatally in infant hippocampus and frontal cortex to levels as high as in the adult (Marcusson *et al.*, 1984a, 1984b).

### *The barrel field as a model system for the study of serotonergic impact on morphogenesis*

The barrel field of the rodent somatosensory cortex has long served as a model system to study cortical patterns

of ascending sensory innervation in development and their plastic responses to altered afferent sensory information (Jeanmonod *et al.*, 1981; Killackey, 1982; Killackey *et al.*, 1995; Erzurumlu and Kind, 2001). Sensory information travels from the whisker pad via the trigeminal nucleus in the brainstem and the ventrobasal nucleus of the thalamus to form an anatomically distinct area in parietal somatosensory cortex (see Figure 1). Individual whiskers have 'barrel-shaped' cellular clusters in layer IV of the somatosensory cortex. The clustering of neurons in barrels first becomes visible around postnatal days 5–7 in mouse and rat, and only fully develops if their afferent sensory inputs are properly developed and maintained (Jeanmonod *et al.*, 1981; Killackey, 1982; Schlaggar and O'Leary, 1994; Killackey *et al.*, 1995; Erzurumlu and Kind, 2001). For instance, if input from a row of whiskers is removed early postnatally (see Figure 1), then adjacent, 'active' whiskers will take over the cortical 'barrel' space vacated by the inactive thalamocortical afferents in the deafferented row.

The current literature leaves little doubt that a normal 5-HT innervation and synaptic tone serve an important role in establishing the proper thalamocortical connectivity and cortical cytoarchitecture that supports the barrel

**Figure 1** Schematic of the whisker-to-barrel pathway. Sensory information from the whisker pad on the mouse snout is conveyed to the cerebral cortex via the trigeminal nerve to the trigeminal nucleus, then to the ventrobasal thalamus and to the barrel field in layer IV of somatosensory cortex (left-hand panel). All along this pathway, the precise somatotopy is preserved such that 'whisker maps' are present in the trigeminal nucleus (barrelettes), the thalamus (barreloids) and cortex (barrels). The cortical representations were named barrels due to their 'barrel' shape when viewed in sections cut in the coronal plane. In flattened sections that are cut through layer IV, barrels are formed by a clustering of neurons around a zone with fewer cells or 'hollows', where the thalamocortical axons travel. The upper-right schematic shows the positions of straddler ( $\alpha$ – $\gamma$ ) and the large barrels in rows A–E (shown in lighter gray), and was drawn from cytochrome-oxidase stained barrel field. This barrel map is altered after neonatal whisker follicle ablation of whiskers C<sub>1</sub>–C<sub>4</sub> (lower-right panel). As a result of this, the barrels in row C shrink, while those in adjacent rows B and D expand.

field in rat and mouse cortex. Moreover, too much or too little serotonin disrupts thalamocortical terminal fields and barrel formation, albeit with somewhat different results. Studies by Blue and colleagues, in rat, first demonstrated that systemic serotonergic *depletions* at birth, using injections of the substituted amphetamine parachloroamphetamine (PCA), delays the development of barrel formation in cortex (Blue *et al.*, 1991). Others subsequently showed that neonatal systemic 5,7-DHT injections reduce cortical serotonin by 75–80 percent in rat and reduce the size and activity of thalamocortical terminal fields without reducing the overall size of cortex or the barrel field (Bennett-Clarke *et al.*, 1994; Turlejski *et al.*, 1997; Rhoades *et al.*, 1998).

Increases in serotonin availability, likewise, alter barrel formation. Several groups have used monoamine oxidase A (MAOA) inhibition via chorgyline and/or MAOA<sup>-/-</sup> mice to increase 5-HT availability. Both paradigms show increased barrel size as well as poorly differentiated barrels (Vitalis *et al.*, 1998, 2002; Boylan *et al.*, 2000b; Alvarez *et al.*, 2002). Another study reported the absence of barrel formation and thalamic afferent patterns, altogether, in MAOA<sup>-/-</sup> mice (Cases *et al.*, 1996). Instead of forming clusters that innervate selected ‘barrels’ in layer IV of somatosensory cortex, thalamocortical afferents maintain a uniform distribution in MAO<sup>-/-</sup> mice (Rebsam *et al.*, 2002). Similar effects are seen using the serotonin uptake inhibitor (SSRI) paroxetine (Xu *et al.*, 2004) or using genetically altered mice lacking the 5-HT uptake pump (Salinchon *et al.*, 2001; Esaki *et al.*, 2005). Importantly, effects of increased cortical 5-HT, via inhibition of reuptake or metabolism, can be reversed by lowering cortical 5-HT availability, pharmacologically or via double knockout mutations, thus indicating that alterations in barrel-field formation and plasticity are indeed specific to altered serotonergic tone (Young-Davies *et al.*, 2000; Salinchon *et al.*, 2001; Rebsam *et al.*, 2002, 2005). The 5-HT<sub>1B</sub> receptor, in particular, has emerged as mediator of the developmental serotonergic effects. Crossing either 5-HTT or MAOA knockout mice with 5-HT<sub>1B</sub><sup>-/-</sup> mice normalizes afferent thalamic branching patterns and barrel-field formation (Salinchon *et al.*, 2001; Rebsam *et al.*, 2002). Pharmacological stimulation of the 5-HT<sub>1B</sub> receptor, conversely, elicits disruptions of barrel-field formation reminiscent of increased 5-HT availability (Young-Davies *et al.*, 2000).

The current concept of how 5-HT levels and 5-HT<sub>1B</sub> receptor stimulation modulate thalamocortical target formation in cortex is based on serotonergic modulation of glutamate receptors. 5-HT<sub>1B</sub> receptors inhibit glutamate activity or release in thalamocortical afferents (TCAs) *in vivo* and *in vitro* (Rhoades *et al.*, 1994; Laurent *et al.*, 2002). Thus, if 5-HT<sub>1B</sub> receptors are present, glutamate

receptors are inhibited by the *excessive* 5-HT caused by the SERT or MAO KOs. When 5-HT<sub>1B</sub> receptors are inhibited or knocked out, along with the others, although 5-HT levels remain high, TCA activity is increased and barrel boundaries are maintained.

Modulation of glutamatergic postsynaptic effects is also compatible with a number of reports of altered cortical neuronal differentiation and cytoarchitectonic maturation. Tryptophan restriction, which reduces cortical 5-HT synthesis, appears to increase dendritic branching in cortical pyramidal cells and increase dendritic spines as well (González-Burgos *et al.*, 1996). The latter findings are compatible with ours showing increases in cortical width after focal serotonergic depletions with 5,7-DHT injections into the medial forebrain bundle in Balb/CbyJ mice (Hohmann *et al.*, 2000).

However, other studies present conflicting findings. For example, Altamura and colleagues reported increases in cortical width in 5-HTT knockout mice, on a C57Bl6 background, with increased levels of 5-HT (Altamura *et al.*, 2007). Likewise, Vitalis and colleagues recently showed that late-embryonic, PCA-mediated 5-HT depletions lead to reductions in the dendritic arborization of cortical layer III and V pyramidal cells (Vitalis *et al.*, 2007). An earlier study reported delays in the differentiation of cortical layers following neonatal 5,7-DHT injections (Osterheld-Haas and Hornung, 1996). Such discrepancies in effect on dendritic growth may be the result of measuring at different intervals or ages after the 5-HT alteration, or of confounding factors such as sprouting of dopaminergic fibers, following serotonergic depletions (Benes *et al.*, 2000). For example, we have observed in our own studies that the increases in the width of selected cortical layers in young adult mice attenuate with increased age (Hohmann *et al.*, 2000, 2007).

Direct 5-HT effects on thalamocortical efferent outgrowth have also been observed *in vitro*. 5-HT stimulation enhances thalamic neuron process outgrowth (Lieske *et al.*, 1999; Lotto *et al.*, 1999), and this effect is sensitive to impulse inhibition via tetrodotoxin (TTX) and mimicked by 5-HT<sub>1B</sub> agonists (Lotto *et al.*, 1999). Extrapolating from these observations, absence of 5-HT<sub>1B</sub> receptor activation would decrease thalamocortical fiber growth into cortex. Thus, depending on the availability of serotonin and on 5-HT<sub>1B</sub> receptor occupancy, thalamocortical afferent ingrowth into cortex is either accelerated or slowed. Such a mechanism would be compatible with a delay in barrel formation after neonatal 5-HT depletion (Blue and Molliver, 1989) and reduction of barrel size (Bennett-Clarke *et al.*, 1994; Rhoades *et al.*, 1998). It remains to be established how postsynaptic glutamatergic and presynaptic growth regulatory mechanisms, modulated by 5-HT, interact to effect the normal formation of the barrel field.

There also are studies of serotonin depletion that point towards a postsynaptic mediation of cortical changes that may be independent of afferent thalamocortical activity. Studies by Rhodes and colleagues suggest that the decrease in barrel size after systemic 5,7-DHT lesions at birth is not dependent on afferent activity, since treatment with TTX does not alter it (Rhoades *et al.*, 1998). Boylan *et al.* (2001) did not detect effects of NMDA receptor blockage on barrel-field plasticity, but that stands in stark contrast to studies by Schlaggar *et al.* (1993). *In vitro* studies have shown that serotonin can directly affect the survival and differentiation of cortical neurons (Dooley *et al.*, 1997; Lavdas *et al.*, 1997). Such effects are more likely mediated by 5-HT<sub>2</sub>- and 5-HT<sub>3</sub>-type receptors. A confound of comparing *in vitro* with *in vivo* studies of the developing cortex is, of course, knowing whether added 5-HT concentrations *in vitro* represent reduced, normal or elevated levels *in vivo*. Thus, it is noteworthy that Lavdas and colleagues saw increased cortical neuron survival in organotypic cultures with co-cultured nucleus raphe neurons (Lavdas *et al.*, 1997). Decreased apoptosis of cortical neurons has also been described, furthermore, in 5-HTT KAO mice where 5-HT is increased (Persico *et al.*, 2003). Increased apoptosis occurs in genetic constructs missing the vesicular 5-HT transporter, which renders 5-HT nearly absent and is blocked by MAOA inhibition (Stankovski *et al.*, 2007).

### Visual cortex

For the past 50 years, kitten visual cortex also has been used to study neurotransmitter modulation of morphological and physiological correlates of use-dependent cortical plasticity. There have been many excellent reviews over the years describing this paradigm, which allows for the morphological and electrophysiological assessment of peripheral visual influences on the patterning of visual inputs (Blakemore and Mitchell, 1973; Wiesel, 1999; Daw and Beaver, 2001; Taha and Stryker, 2005). Basically, thalamocortical afferents from the lateral geniculate nucleus segregate into columns with differential responsiveness to visual input from the left and right eye over the course of the first 2–3 months after birth, also named the ‘critical period’. Monocular deprivation of vision from either eye during this critical period allows cortical responsiveness to drift towards the eye that is receiving visual input, effectively disconnecting the occluded eye from cortex. The extent of this ‘ocular dominance shift’ depends on the duration and timing of eye occlusion. This process is clearly dependent on excitatory glutamatergic neurotransmission, particularly NMDA receptor activation (Gu *et al.*, 1989; Bear *et al.*, 1990; Rauschecker, 1991a).

The development of the ‘ocular dominance columns’ in cat visual cortex has been regarded as a classical model of cortical learning and memory formation in that it is susceptible to both long-term potentiation (LTP) and long-term depression (LTD) (Rauschecker, 1991a; Kirkwood *et al.*, 1995; Johansen-Berg and Walsh, 2001).

The effect of monoaminergic and cholinergic modulation of developmental plasticity became an intense focus of research during the 1980s (Singer and Rauschecker, 1982; Sillito *et al.*, 1985; Gordon *et al.*, 1988). Based on the similarities in timing and adult modulatory properties on cortical synapses, Gu and Singer conducted a comprehensive assessment of 5-HT effects on ocular dominance plasticity (Gu and Singer, 1995). They showed that infusion of 5,7-DHT into visual cortex at 1 month postnatally, combined with 1 week of eye occlusion in the kittens, substantially inhibited ocular dominance shift to the open (not occluded) eye. This was specific to 5-HT depletion, since comparable effects were elicited with comprehensive 5-HT receptor blockage. Although neither 5-HT<sub>1</sub> nor 5-HT<sub>2</sub> receptor blockage alone inhibited plasticity, combined cortical application of the antagonists methysergide and ketanserin did effectively block the drift of responsive cortical cells towards the open eye. Other groups have since confirmed that serotonergic antagonists can interfere with ocular dominance plasticity (Wang *et al.*, 1997). The 5-HT<sub>2C</sub> receptor has become most closely associated with the regulation of OD plasticity in cat, as well as with the mediation of, curiously, both LTP and LTD (Dyck and Cynader, 1993; Wang *et al.*, 1997; Kojic *et al.*, 2000, 2001). In his 2000 Commentary in *PNAS*, Kirkwood elucidates this apparent conundrum. Not only are serotonergic receptors distributed in a highly laminar and developmentally changing manner; 5-HT<sub>2C</sub> receptors actually also have a patterned, columnar appearance even within the developing layer IV in kitten occipital cortex (Kirkwood, 2000). Thus, serotonin has the ability to transiently modulate plasticity during the critical period in kitten cortex in a manner that interacts with and shapes the microcolumnar arrangement of the cortex (Kirkwood, 2000). Modulation of plasticity via 5-HT<sub>2C</sub> receptors has also been reported in the rat hippocampus (Tecott *et al.*, 1998), and 5-HT attenuates LTP in slice preparations of immature rat visual cortex via receptors that aren’t clearly classified (Edagawa *et al.*, 2001).

5-HT<sub>1</sub> receptors also appear to play a role in the shaping of cat visual cortex. Mower (1991) showed a selective up-regulation of 5-HT<sub>1</sub> receptors in the visual cortex of dark-reared cats that spared other cortical areas (Mower, 1991). In rat visual cortex, neonatal removal of visual input via enucleation (eye removal) also increases the number of 5-HT<sub>1B</sub> receptors, and neonatal 5,7-DHT injections lead to a transient increase in 5-HT<sub>1B</sub> receptors (Sari *et al.*, 1999).

It has been shown that the SSRI fluoxetine, which is used to treat depression in humans, can augment visual plasticity in rats, even in the adult (Maya Vetencourt *et al.*, 2008). Besides blocking serotonin uptake, fluoxetine is also known to interact directly with 5-HT<sub>2C</sub> receptors (Ni and Miledi, 1997).

So what is it that we have learned from the study of serotonergic regulation of cortical plasticity in the rodent barrel field and cat visual system? Cortical plasticity is clearly a highly complex process that cannot easily be comprehended by observing single receptor related effects in isolation. 5-HT<sub>1</sub>-type and 5-HT<sub>2</sub>-type receptor families both influence this process in the barrel field and visual cortex, and 5-HT<sub>1B</sub> and 5-HT<sub>2C</sub> receptors have emerged as the two most likely candidates to mediate serotonergic responses. These receptors apparently have different locations in the developing nervous system. The 5-HT<sub>1B</sub> receptor is located on thalamocortical afferents in the barrel field, at least in mouse and rat (Bennett-Clarke *et al.*, 1993; Laurent *et al.*, 2002). This is consistent with unrelated observations that this receptor apparently localizes predominantly to axonal terminals (Sari, 2004). On the other hand, in the somatosensory and visual cortex of rodents and felines, the 5-HT<sub>2C</sub> receptor is clearly localized postsynaptically, on cortical neurons, and influences LTP and LTD in these neurons (Kirkwood, 2000; Edagawa *et al.*, 2001). Both model systems also show that cortical serotonergic modulation is mediated via the NMDA receptor mechanisms. Thus, the emerging picture is one of a dual serotonergic influence on both afferent thalamocortical fiber ingrowth into cortex (i.e., fasciculation, target selection) and the ability of the arriving fibers to activate their cortical targets (i.e., LTP/LTD induction, synapse formation and elimination). Removing serotonergic afferents during critical periods of cortical plasticity in visual cortex clearly arrests the ability of cortex to reorganize itself in response to altered sensory stimulation, hence inappropriate map formation. While changes in serotonergic tone affect the timing and ultimate shape of the barrel field, it is less clear in this paradigm how they affect cortical reorganization in response to altered sensory input. However, these barrel-field studies were performed after whole body changes in 5-HT or receptors, opening up the possibility that other modulatory systems were affected as well, perhaps compensating for plasticity disruptions. In contrast, 5-HT levels and receptor function were manipulated with direct infusions into the visual cortex, limiting the possibilities of compensatory effects within the timeframe of study. Thus, the proof of concept, in rodent, might be a localized depletion of the relevant cortical areas, such as our focused lesions of the afferent 5-HT innervation to cortex, described below.

## Serotonin in ASD

### *Brief characterization of ASD*

ASD encompasses a spectrum of developmental brain disorders characterized by deficits in social and communication behavior, perseveration or stereotyped behavior, altered sensory-motor performance and a variety of aspects of altered cognitive performance and emotional responsiveness (DeMyer, 1975; Rapin, 1991; Gillberg, 1999; Lord *et al.*, 2000; Dawson *et al.*, 2002a; Baron-Cohen, 2004; DiCicco-Bloom *et al.*, 2006; Landa *et al.*, 2007). ASD is approximately four times as prevalent in males compared to females (Murcia *et al.*, 2005; Landa, 2008). In the absence of a clear neurobiological understanding of the disorder and without any biomarkers, an ASD diagnosis is still entirely based on a pattern of behavioral deficits and alterations compared to typically developing children. ASD is currently regarded as predominantly of genetic origin, based on a 70 percent or larger concordance among monozygotic twins (Abramson *et al.*, 1992; Buitelaar and Willemsen-Swinkels, 2000; Baron-Cohen, 2004), yet sporadic occurrences of autism still outnumber autism in multiplex families where a pedigree can be established (Trottier *et al.*, 1999). Part of the problem is that it is nearly impossible to investigate environmental influences on ASD in the human population in the absence of a clearly defined etiology and neurobiology of the disorder (Serajee *et al.*, 2004; Arndt *et al.*, 2005; Santangelo and Tsatsanis, 2005; Bello, 2007; Newschaffer *et al.*, 2007; Pardo and Eberhart, 2007). Meanwhile, hundreds of genes and restriction enzyme polymorphisms have been linked to ASD in the human population (Wassink and Piven, 2000; Cook, 2001; Muhle *et al.*, 2004; Polleux and Lauder, 2004), and the list is growing steadily. Many of these candidate genes have become the focus of investigation in animal models, *in vitro* and *in vivo*, and a number of them have been shown to influence morphological or behavioral endophenotypes shared with ASD (see, for example, Wassink *et al.*, 2001, 2004; Andres, 2002; Bernardet and Crusio, 2006; Nishijima *et al.*, 2006; Paylor *et al.*, 2006; Kuemerle *et al.*, 2007; Jamain *et al.*, 2008). It is clear, however, that no one single gene can be linked to ASD as causative; this is a polygenetic disorder with, at best, a final common neurobiological phenotype (Gillberg, 1999; Arndt *et al.*, 2005; Santangelo and Tsatsanis, 2005). It is also increasingly becoming accepted that environmental influences likely serve as triggers for the disorder in individuals with a vulnerable genotype (Trottier *et al.*, 1999; Herbert *et al.*, 2006; Bauer *et al.*, 2007; Pardo and Eberhart, 2007). We will begin, below, with a description of the most prevalent neurobiological deficits in ASD, particularly as they pertain to cerebral cortex.

### *Developmental neurobiology of ASD*

Although some specialists are now able to diagnose ASD with some certainty as early as 12 to 18 months postnatally, the disorder is still typically diagnosed between 2 and 3 years of age, when social and communication deficits are becoming overwhelmingly obvious to caregivers (Osterling *et al.*, 2002; Landa, 2007, 2008). At this time in development, there is already a significant increase of cortical volume in children with ASD, which in the white matter volume is about a 10 percent change (Courchesne *et al.*, 2001; Courchesne, 2002, 2004; Sparks *et al.*, 2002; Carper and Courchesne, 2005; Hazlett *et al.*, 2005). Volume increases have been confirmed by many additional studies in older children and adults, yet comparisons of such studies suggest that brain volume decreases with age, leaving the margin of difference closer to 1 percent (Aylward *et al.*, 2002; Herbert *et al.*, 2004; Redcay and Courchesne, 2005; Mostofsky *et al.*, 2007; Wassink *et al.*, 2007). Head circumference is also increased in the toddler years and attenuates with age (Aylward *et al.*, 2002). The cortical areas that show the most prominent increase in volume of both white and gray matter are the frontal and temporal lobes, while the least change is seen in occipital cortex. Frontal and temporal cortical areas display altered event-related potentials and fMRI activation to social stimuli as early as ages 2–4 years, demonstrating the functional significance of the anatomical findings (Boddaert and Zilbovicius, 2002; Dawson *et al.*, 2002b; Kuhl *et al.*, 2005; Courchesne *et al.*, 2007; Knaus *et al.*, 2008; Muller, 2008). Volume changes in parietal areas have not received as much attention, but significant evidence of increased gray and white matter volume is present there as well (Courchesne *et al.*, 1993; Saitoh and Courchesne, 1998; Mostofsky *et al.*, 2007).

Cortical gray matter cytoarchitecture is also disturbed in autism. *Post-mortem* microscopic evaluation of brain tissue from adults with autism demonstrates abnormalities in cerebral cortical development that include increased cortical thickness and neuronal density, neuronal disorganization with some suggestions of abnormal migration, poorly differentiated gray–white matter boundaries, and increased number of neurons in the white matter (Bailey *et al.*, 1998; Kemper and Bauman, 1998). While the former changes are not easily reconciled with any particular functional network in cortex, Casanova and colleagues have reported changes in minicolumns in frontal, temporal and, most recently, auditory cortex that point towards specific information-processing deficits. Minicolumns in ASD are smaller, more numerous and less compact in adolescent subjects compared to those of control subjects (Casanova *et al.*, 2002; Buxhoeveden *et al.*, 2006). Alterations in the size and cellular distribution

within cortical minicolumns in autism likely reflect disturbances in the processing of thalamic inputs to cortex that are rooted in the ontogeny of these connections (Buxhoeveden and Casanova, 2002). In normal cortical development, cortical minicolumns are generally regarded as the smallest cortical processing unit that self-assembles according to Hebbian principles (Shenoy *et al.*, 1993; Favorov and Kelly, 1994). In the sensory and motor cortex of the mature organism, minicolumns are responsible for generating basic receptive field properties, and combine to constitute the columnar processing arrangements originally described by Hubel and Wiesel, Mountcastle and colleagues (see Favorov and Kelly, 1994; Amirikian and Georgopoulos, 2003). The functional significance of minicolumns in fronto-cortical areas has been demonstrated in a modeling study (Koene and Hasselmo, 2005). Recent psychometric studies in ASD corroborate observations of altered minicolumn anatomy by demonstrating impairments in sensory perceptual changes in adults with ASD (Tommerdahl *et al.*, 2008). Furthermore, altered minicolumns are consistent with evidence for abnormal sensory cortical maps in autism, including modifications in cortical sulcal maps (Levitt *et al.*, 2003) and visual–motor maps (Muller *et al.*, 2003), deficits in the development of cortical sound processing (Gage *et al.*, 2003), and problems with face recognition (Pierce *et al.*, 2001; Dawson *et al.*, 2002b). Studies by Janusonis and colleagues have suggested that 5-HT innervation of reelin containing Cajal Retzius (CR) cells is involved in appropriate maturation of the columnar arrangement in cortex (Janusonis *et al.*, 2004).

As recently pointed out by Courchesne, a fundamental problem in understanding the developmental pathology of ASD is that the vast majority of current brain studies have been conducted in older children or adults (Courchesne *et al.*, 2007). Thus, with the exception of the abovementioned measurements of cortical volume and head circumference in toddlers, at the age of first diagnosis most current neuropathology is looking at a brain well after the initial developmental disruptions – a cortex that has already made adjustments to altered structure and function. In comparison with the experimental model systems discussed in the first section of this review, this also would be a cortex past the ‘critical period’ for developmental plasticity. To better illustrate this, a brief review of human cortical development is merited.

The processes of neocortical neuronal differentiation, dendritic elaboration and axon outgrowth substantially occur between late gestation and school age, but extend into adolescence in frontal cortical areas (for reviews, see Huttenlocher, 1990; Mrzljak *et al.*, 1992; Kostovic and Judas, 2002; Courchesne *et al.*, 2004; Courchesne and Pierce, 2005; Kostovic and Jovanov-Milosevic, 2006; Bystron *et al.*, 2008). The cortical plate forms in humans

around gestational weeks 6–7 (Marin-Padilla, 1970, 1978; Mrzljak *et al.*, 1992), and neuronal migration into the cortex is concluded by gestational weeks 24–26 when synaptogenesis commences (Rakic, 1988; Bystron *et al.*, 2008). The bulk of neuronal differentiation and synapse formation occurs postnatally, and shows regional variations along a posterior to anterior gradient (Huttenlocher, 1979, 1984; Huttenlocher *et al.*, 1982; Huttenlocher and Dabholkar, 1997). For example, according to electron microscopic (EM) quantifications of synaptic profiles, peak synapse formation in visual cortex occurs roughly around 1 year of age, while in frontal cortex, synapse formation continues to increase for another couple of years (Huttenlocher and Dabholkar, 1997). As recently illustrated by Courchesne and colleagues, and according to Golgi data from earlier studies, the dendritic expansion of cortical pyramidal neurons closely mirrors the increase in synapse formation (Courchesne *et al.*, 2007). In subsequent postnatal years, synapses are pruned in cortex to fine-tune functional connectivity, a process that in frontal areas lasts into the second decade of life (Huttenlocher, 1984; Huttenlocher and Dabholkar, 1997; Courchesne *et al.*, 2007). Studies of molecular synaptic markers have essentially confirmed these EM studies but contributed some additional information about synapse type. Synapse numbers increase into late childhood (10 years of age), as indicated by synaptophysin quantification, while the peak number of presumed glutamatergic synapses, as labeled by PSD-95, is reached earlier but then decreases (Glantz *et al.*, 2007). Western blot analysis of complexin 1 (CX1) and complexin 2 (CX2), proteins associated predominantly with inhibitory (GABAergic) of excitatory (glutamatergic) synapses respectively, substantiates the impression that excitatory synapses in cortical development peak at around 10 years of age, while inhibitory synapses continue to increase into adulthood (Salimi *et al.*, 2008). Moreover, glucose utilization, which also is regarded as an indicator of cortical synaptic activity, increases between birth and 3 years of age to nearly three times adult levels, followed by a decrease after age 8 years (Chugani, 1998; Muzik *et al.*, 1999). Chugani has likened this glucose utilization plateau between the ages of 3 and 8 years to the critical period in animal models (Chugani, 1998).

The temporal and regional differences in cortical synaptogenesis can seriously confound the analysis of volume measurements in ASD, compared to typical development, and may have led, in past studies, to an underestimation of quantitative gray-matter changes. Several groups have recently used MRI technology to assess regional brain growth in typically developing children pre- and postnatally (Sowell *et al.*, 2001; Kostovic and Judas, 2002). Kostovic demonstrated a 50 percent increase in cortical

gray matter, between gestational week 29 and term, which he attributed to afferent ingrowths of subcortical and cortico-cortical axons, concomitantly with the expansion of cortical neuropil, as dendritic branches and synapses expanded (Kostovic and Judas, 2002). Sowell and colleagues analyzed cortical thickness in the same group of typically developing children at 5 and again at 11 years of age (Sowell *et al.*, 2001). This study revealed a complex pattern of intermingled areas of gray-matter expansions and contractions in development, presumably as a consequence of fine-tuning and pruning of cortical connections along regionally specific timelines.

An emerging neurobiological concept is that ASD represents a failure in the development of networks (Rubenstein and Merzenich, 2003; Belmonte *et al.*, 2004; Dong and Greenough, 2004; Courchesne *et al.*, 2007; Minshew and Williams, 2007). Neuropathologies such as altered minicolumns and cortical map formation, in conjunction with transient increases in cortical volume, all point towards developmental disruptions of cortical circuitry formation and pruning. As illustrated in the preceding paragraph, connections between cortical neurons and their thalamic afferents begin to form in the late gestational period, after neuronal generation has largely concluded in cortex, and they continue after birth. Connections between cortical regions commence to form and mature for years postnatally, with networks in frontal cortical areas being the latest to reach maturity, in adolescence. Thus, based on the currently available neuropathology data, cortical development appears to proceed normally until the late gestational period when afferent innervation and synapse formation begins to be disrupted, as suggested by altered minicolumn formation. Such cortical neuropathologies in ASD are compatible with the disruptions of serotonergic modulatory influences in cortical network formation, as outlined in the first section of this chapter.

### ***Evidence for serotonergic imbalances in ASD***

Substantial evidence supports altered serotonergic homeostasis in ASD. A longstanding literature has shown *increased* platelet serotonin levels in both children and adults with ASD (Anderson *et al.*, 1990; Cook, 1990; Burgess *et al.*, 2006; Lam *et al.*, 2006). In contrast, cortical serotonergic innervation appears to be transiently *decreased* during early postnatal development, and perhaps also prenatally. Chugani and colleagues have shown an altered developmental trajectory of serotonergic innervation to the cerebral cortex in ASD (Chugani *et al.*, 1999). Using positron emission tomography (PET) imaging of a tryptophan analog, they found that young children

with autism do not display the developmental peak in brain 5-HT synthesis capacity seen in typically developing children; this attenuation correlated with altered language development (Chugani *et al.*, 1999; Chandana *et al.*, 2005). Boys with autism also showed specific decreases in 5-HT synthesis in the dentato-thalamocortical pathway, with simultaneous increases in the contralateral dentate deep cerebellar nucleus (Chugani *et al.*, 1997). Interestingly, in adults with ASD, serotonin synthesis has normalized or may even show increases (Chugani *et al.*, 1999; Chandana *et al.*, 2005). The significance of these findings has been highlighted recently by the demonstration of decreased SERT binding, particularly in frontal cortex, in young children with ASD, using single photon emission computed tomography (SPECT) (Makkonen *et al.*, 2008). Lowered SERT is suggestive of decreased serotonergic fiber densities in the cortex of these young children. Furthermore, studies in adults with Asperger's syndrome show a significant decrease in cortical 5-HT<sub>2A</sub> receptors (Murphy *et al.*, 2006). Thus, while 5-HT levels may normalize or even increase in adults with ASD, their postsynaptic receptive mechanisms still may be down-regulated.

There is substantial genetic evidence for altered serotonin homeostasis in ASD and family members. This includes promoter region polymorphisms (5-HTTLPR) of the 5-HTT gene SLC6A4 (Cook *et al.*, 1997; Yirmiya *et al.*, 2001; Conroy *et al.*, 2004; Devlin *et al.*, 2005; Sutcliffe *et al.*, 2005; Guhathakurta *et al.*, 2006; Koishi *et al.*, 2006) that can correlate significantly with cortical gray-matter volume in young children with ASD (Wassink *et al.*, 2007), or with a rigid-compulsive endophenotype (McCauley *et al.*, 2004). Other genotype-phenotype interactions for the 5-HTTLPR also are observed in ASD (Brune *et al.*, 2006). Promotor region polymorphisms also may be associated with peripheral hyperserotonemia in a subset of patients (Anderson *et al.*, 2002; Coutinho *et al.*, 2004). Linkage disequilibrium involving alleles for the 5-HT<sub>2A</sub> receptor has been described as well (Veenstra-VanderWeele *et al.*, 2002; Cho *et al.*, 2007). Moreover, Hu and colleagues demonstrated increased SERT expression in peripheral lymphocytes is associated with ASD phenotype in monozygotic twins who are discordant for autism (Hu *et al.*, 2006).

Observation of elevated peripheral serotonin in individuals with ASD and early central-developmental decreases may not be as contradictory as they seem. As described in more detail below, exposure of rats to a serotonergic agonist from mid-gestation to adolescence, leading to elevations in pre- and postnatal peripheral 5-HT levels, actually resulted in a loss of central serotonergic innervation in the pups, presumably due to autoregulation via 5-HT<sub>1A</sub> receptors (Whitaker-Azmitia, 2005). Additionally, 5-HT<sub>1A</sub>

receptor knockout mice present with platelet hyperserotonemia in development and adulthood, but show transient, early, postnatal serotonin decreases in the brain (Janusonis *et al.*, 2006). Moreover, studies of gestational tryptophan hydroxylase inhibition and, more recently, studies involving tryptophan-1 deficient (tph-1<sup>-/-</sup>) mice have demonstrated that peripheral serotonin levels and normal brain morphogenesis in offspring are a direct consequence of peripheral and maternal serotonin availability during gestation (Lauder *et al.*, 1981; Cote *et al.*, 2007). The mechanisms that regulate the relationship between CNS and peripheral serotonergic synthesis and control are not understood, and clearly much work is needed here.

Likewise, information regarding the development of the serotonergic innervation in typically developing human cortex is limited at present. Using the serotonin transporter (SERT) and vesicular transporter (VMAT2) as markers for 5-HT, fibers from the raphe are shown to enter the immature cortex around gestational week 13 (Verney *et al.*, 2002). A transient gestational presence of SERT immunoreactive fibers in the internal capsule suggests transient SERT expression on thalamocortical afferents in humans, as observed for other mammals (Verney *et al.*, 2002). Similarly, a peak in 5-HT<sub>1A</sub> receptor expression is observed in the human cortex during gestational weeks 16–22, when thalamocortical fibers first approach and then enter the cortical plate (Bar-Peled *et al.*, 1991). Thus, current data strongly suggest that serotonergic afferents in humans exert similar morphogenetic functions in cortex as seen for several mammalian animal models.

### ***Experimental approaches to testing a serotonergic hypothesis of ASD***

Only a few laboratories have devised experimental paradigms that directly address the 'serotonergic hypothesis' that is, the role of serotonin in the etiology of ASD. We have developed a mouse model based on the hypothesis that selective neonatal serotonergic depletions of cortex will produce morphological and behavioral pathologies consistent with ASD. In this model, we have deliberately limited 5-HT manipulations to cortical areas of the forebrain in order to isolate resulting behavioral deficits. Our goal has been to distinguish alterations that are due directly to serotonergic depletion, from changes that might be secondary effects of 5-HT depletion on other afferent neuromodulatory systems, such as (for example) catecholaminergic or cholinergic afferents, or the HPA axes (Berger-Sweeney *et al.*, 1998; Hohmann *et al.*, 2000, 2007; Boylan *et al.*, 2007). As shown in Figure 2A, we neonatally inject the neurotoxin 5,7-DHT into the medial forebrain bundle to provide a selective, albeit transient,

serotonergic denervation of cortex and hippocampus (Figures 2C, 2D). Our earliest studies (Hohmann *et al.*, 2000) demonstrated significant, quantifiable alterations in the cortical cytoarchitecture of adult mice following the neonatal serotonergic depletion. These changes were dimorphic, and more substantial in males. Subsequent work (Boylan *et al.*, 2007; Hohmann *et al.*, 2007; Blue *et al.*, 2008) revealed a significant increase in early cortical volume that is no longer apparent by adulthood (see Figure 2B). Altered cortical morphogenesis is also accompanied by changes in cortical excitatory amino acid neurotransmission consistent with altered development of cortical networks (Boylan *et al.*, 2007). While we are still in the process of characterizing the full range of morphological and molecular changes that account for altered cortical development, we have observed increased immunoreactivity for glial fibrillary protein, possibly an indicator of a neuro-inflammatory response, in the cortex of 5-HT-depleted mice at the time of the transient volume increase (Figures 2E, 2F; unpublished observations). Morphological alterations in our mouse model are accompanied by substantial changes in social and cognitive behaviors, and these behavioral abnormalities are also more prevalent in males than females. As adults, lesioned mice show learning deficits in a socially motivated food preference task, along with altered social interactions with conspecifics and increased stereotypical behaviors (Boylan *et al.*, 2007). Preliminary data suggest that social behaviors are altered as early as the first week postnatally, when cortical volume increases are measured (unpublished observations). The neonatally 5-HT-depleted mice also show, as adults, substantial neophobia within a spatial exploratory context that occurs in the absence of generalized anxiety (Hohmann *et al.*, 2007). Additional tests also indicate sensory processing abnormalities and problems with impulse inhibition in the lesioned mice (Berger-Sweeney *et al.*, 1998; Boylan *et al.*, 2007; Hohmann *et al.*, 2007).

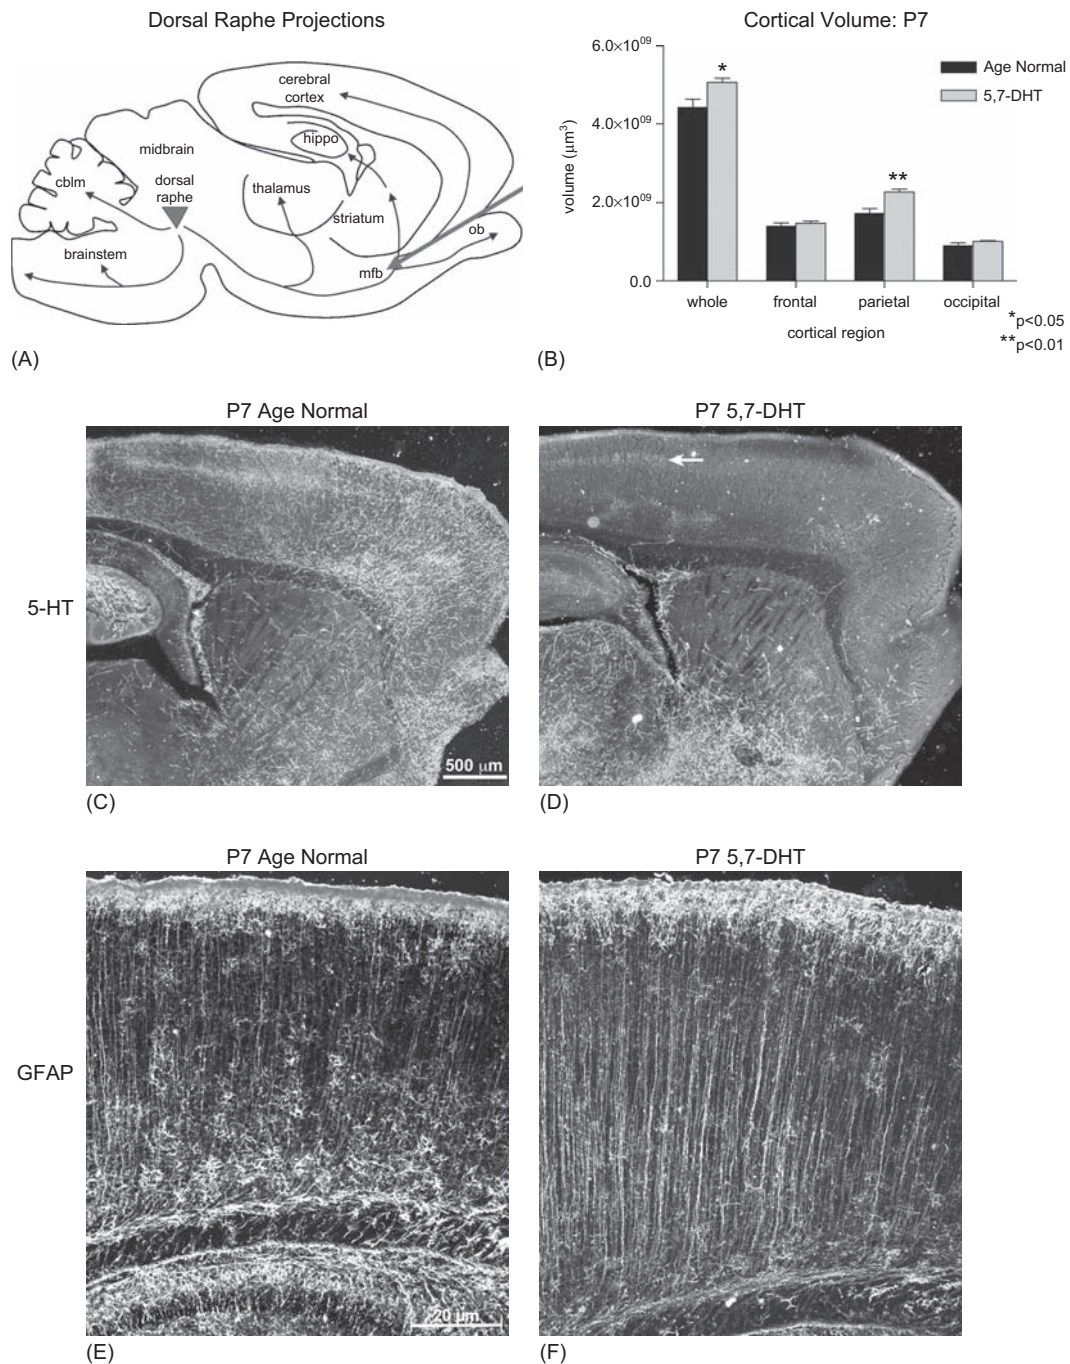

Whittaker-Azmitia and colleagues devised a mouse model aimed at testing the effects of hyperserotonemia on brain and behavioral development, by treating pregnant rats with the serotonin agonist 5-methoxytryptamine (5-MT) between gestational day 12 and various postnatal time periods (Kahne *et al.*, 2002). As already stated above, while such treatment did increase peripheral 5-HT levels in the offspring of such treated dams, brain 5-HT was actually decreased throughout the critical periods of cortical differentiation and synaptogenesis. These rats displayed behavioral alterations compatible with the ones seen in our neonatally 5-HT depleted mice, such as altered sensory responsiveness and stereotopies (Whittaker-Azmitia, 2005). In addition, the Whittaker-Azmitia group has described substantially

altered mother–pup interactions, post-injection seizures and metabolic disturbances, as indicated by magnetic resonance spectroscopy (MRS) studies in the animals as adults (Kahne *et al.*, 2002; Whittaker-Azmitia, 2005; McNamara *et al.*, 2008). Unlike our neonatal serotonin depletion model, the perinatal 5-MT rats show altered serotonergic homeostasis throughout the brain, and neurochemical changes were observed in the hypothalamus and amygdala, including a decrease in oxytocin in the paraventricular nucleus (Whittaker-Azmitia, 2005; McNamara *et al.*, 2008). Thus, the more encompassing behavioral and neurobiological changes in the perinatally treated rats are compatible with a more severe serotonergic disruption, suggesting that the developing cortex is not the sole target of serotonergic imbalance in ASD.

Genetic models for serotonergic depletion have, to date, not been studied extensively within the context of ASD. Serotonin transporter gene (SERT) knockout mouse models have shown systemically altered 5-HT homeostasis, and have been linked to altered gut function, inflammatory responses, stress responsiveness and anxiety responses (Murphy and Lesch, 2008). Moy and colleagues recently found decreased sociability in mice with such targeted disruptions (Moy *et al.*, 2009), but little can be deduced about brain pathologies in these mice that presumably have substantial increases of 5-HT availability in development. The Pet-1 ETS transcription factor appears to be responsible for the specification of brainstem 5-HT neurons (Hendricks *et al.*, 1999; Hendricks *et al.*, 2003; Scott *et al.*, 2005). Mice with this mutation have an approximately 80 percent reduction of CNS serotonergic innervation; their neurological effects appear relatively mild, although postsynaptic receptors or SERT content were not assessed, making it difficult to deduct the level of functional neurotransmission (Hendricks *et al.*, 2003). Cortical cytoarchitecture appears qualitatively normal, and, behaviorally, increased anxiety and aggression were the most notable observations (Hendricks *et al.*, 2003). Clearly, these models merit further scrutiny.

In addition, a variety of rodent models, designed to test for the effects of specific environmental or genetic manipulations on the development of ASD endophenotypes, coincidentally include altered serotonergic homeostasis. One of the most longstanding ASD models, gestational exposure to valproic acid (VPA), shows altered development of afferent serotonergic innervation to the forebrain, along with behavioral manifestations such as increased stereotopies, altered sensory responsiveness and altered eye-blink reflexes (Miyazaki *et al.*, 2005; Schneider and Przewlocki, 2005; Stanton *et al.*, 2007; Murawski *et al.*, 2009). The engrailed 2 (ENG-2) mouse mutant, studied as a model for homeobox gene involvement in ASD, also displays altered serotonergic innervation to the forebrain

**Figure 2** 5,7-DHT mouse model. (A) Schematic drawing of a parasagittal section through a P7 mouse brain showing the location of the serotonergic neurons in the dorsal raphe and the projections from the raphe to multiple brain regions. Serotonergic axons innervate the hippocampus (hippo) and cerebral cortex via the medial forebrain bundle (mfb). The red arrow indicates the path of the 5,7-DHT injections. cbml, cerebellum; ob, olfactory bulb. (B) The volume of the whole cerebral cortex and parietal regions was greater in 5,7-DHT lesioned mice than in Age Normal controls. (C, D) Dark field photomicrographs show the distribution of serotonergic axons (5-HT) in parasagittal sections of (C) P7 Age Normal and (D) 5,7-DHT lesioned mouse brains. In lesioned mice, there are many fewer afferent serotonergic axons in the cortex and the hippocampus. However, some serotonin remains in thalamocortical terminals due to their transient expression of the serotonin transporter (white arrow). (E, F) The pattern of immunostaining for glial fibrillary acetic protein (GFAP) is shown in the dark field photomicrographs of the cortex in (E) Age Normal and (F) 5,7-DHT lesioned mouse brains. At P7, many of the radial glial fibers remain present, and their density appears higher in the lesioned mice. To see the full color version of this figure please refer to the color plate at the back of the book. Copies produced via our print on demand service do not contain color plates. If your copy does not have the color plate, please go this website to view the figure in color [www.elsevierdirect.com/companions/9780123746344](http://www.elsevierdirect.com/companions/9780123746344)

and cerebellum, suggesting a role of this brainstem segmentation gene in the formation of the raphe nucleus (Cheh *et al.*, 2006; Kuemerle *et al.*, 2007). Mouse models for Fragile X and Smith-Lemli-Opitz, both regarded as disorders on the autism spectrum, show altered 5-HT innervation (Gruss and Braun, 2001; Waage-Baudet *et al.*, 2003; Moy and Nadler, 2008). Interestingly, serotonergic innervation is up- rather than down-regulated in the brain of several of the aforementioned mouse models, confirming the assessment in basic research studies (see first section of this chapter) that too much as well as too little serotonin can be detrimental to forebrain development and function.

### ***Factors that can interact with serotonin homeostasis in ASD***

#### *Neuroinflammatory/neuroimmune interactions*

As Herbert and others have pointed out, ASD is not solely a disorder of altered brain and behavior (Lipkin and Hornig, 2003; Herbert *et al.*, 2006; Herbert and Anderson, 2008; Pessah *et al.*, 2008). Thus, a ‘whole body’ approach may offer further conceptualizations of core deficits and intervention strategies for ASD. Reports of altered immune and digestive function in ASD abound, suggesting that up to 60 percent of patients with ASD have some type of systemic immune dysfunction as part of their cellular or humoral immune response (Posey and McDougle, 2001; Horvath and Perman, 2002; Korvatska *et al.*, 2002; Krause *et al.*, 2002; Licinio *et al.*, 2002; Torres, 2003; Cohly and Panja, 2005; Ashwood *et al.*, 2006; Wills *et al.*, 2007). The most prevalent observations concern altered innate immune responses and an increase in pro-inflammatory cytokines, particularly interleukin-1 (IL-1) and IL-6 and tumor necrosis factor (Gupta *et al.*, 1998; Croonenberghs *et al.*, 2002; Chez *et al.*, 2007; Grigorenko *et al.*, 2008; Jyonouchi *et al.*, 2008). However, there are also reports of an altered inducible immune response and other cytokine changes (Ashwood *et al.*, 2006; Molloy *et al.*, 2006). Since the cited reports concern a mix of measurements in serum, in cerebrospinal fluid or *in vitro* blood cell explants, some contradictory observations might be the product of assessing different compartments as well as differently affected individuals. Recent studies also have provided evidence for a neuroinflammatory response directly in the brain of ASD. Reports show lymphocyte infiltration as well as astroglial and microglial infiltration (Pardo *et al.*, 2005; Vargas *et al.*, 2005). Cytokines/chemokines predominantly of the pro-inflammatory variety, such as MCP-1, IL-6 and TGF $\beta$ 1, which are derived from activated neuroglia, are up-regulated in brain tissues in ASD (Cohly and Panja, 2005;

Pardo *et al.*, 2005; Vargas *et al.*, 2005; Molloy *et al.*, 2006). Gastrointestinal problems in individuals with ASD are linked to an altered ability to absorb nutrients, and are generally of an inflammatory nature (Horvath and Perman, 2002; Wakefield, 2002; Jyonouchi *et al.*, 2005). Thus, there may be a direct connection between digestive dysfunction and immune disruption.

Interestingly, serotonin emerges as a common denominator in both systemic as well as CNS pathologies associated with ASD. Peripherally, serotonin is synthesized by the enzyme Th1 in the enterochromaffin cells of the gut and in enteric neurons, and enters the bloodstream from there to be selectively taken up by platelets (Kiba, 2006; Schroecksnadel *et al.*, 2006; Grundy, 2008). Serotonergic release is involved in the modulation of gut motility and the secretion of intestinal fluids (Ormsbee and Fondacaro, 1985; Kiba, 2006; Li, 2007; Hansen and Witte, 2008). These processes are under vagus nerve control, which in turn receives input from serotonin neurons in the raphe nucleus (Tache *et al.*, 1993; Li, 2007; Kiba, 2006). As mentioned above, mouse constructs with altered systemic serotonergic neurotransmission, such as SERT-null mice, have altered intestinal functions, along with inflammatory responses, stress responsiveness and anxiety response (Murphy and Lesch, 2008). It has been postulated that, under inflammatory conditions, serotonergic modulation of gut activity may become disrupted (Grundy, 2008). However, given that SERT-null mice also show altered inflammatory responses, serotonergic disruptions may also be primary to the occurrence of inflammation. 5-HT is a known immune system regulator (Burgess *et al.*, 2006); it directly binds to receptors on both T- and B-lymphocytes to activate or suppress their function (Meredith *et al.*, 2005; Soga *et al.*, 2007; Levite, 2008). The complete mechanisms for these actions are not currently understood, but the expression of a plethora of different 5-HT receptors on lymphocytes, in addition to the SERT transporter, strongly suggest a complex regulatory network (Meredith *et al.*, 2005). Recent studies suggest that peripheral 5-HT promotes pro-inflammatory responses, along with cellular stimulation and cytokine release (Idzko *et al.*, 2004; Katoh *et al.*, 2006; Kushnir-Sukhov *et al.*, 2006). In particular, 5-HT appears to affect IL6 and TNF $\alpha$  release from a variety of different cell types (Basterzi *et al.*, 2005; Durk *et al.*, 2005; Lieb *et al.*, 2005; Cloez-Tayarani and Changeux, 2007; Menard *et al.*, 2007; Yu *et al.*, 2008). Central serotonin levels are also able to modulate inflammatory conditions in the periphery (Harbuz *et al.*, 1998).

Likewise, cytokine release can regulate the availability of tryptophan, the precursor amino acid used by Th1 in the periphery and Th2 in the CNS to generate serotonin (for extensive review, see Wirleitner *et al.*, 2003;

Schroeksadel *et al.*, 2006a). In particular, interferon- $\gamma$  (INF $\gamma$ ) and IL-2 stimulate the expression of the enzyme indolamine-2,3-dioxygenase [IDO], which degrades tryptophan to generate, among its end-products, kynurenic acid (Wirleitner *et al.*, 2003; Schroeksadel *et al.*, 2006a, b). The physiological 'purpose' of this accelerated catabolism presumably is to reduce protein availability and 'starve' infectious agents while similarly providing regulatory feedback to the immune-response (Schroeksadel *et al.*, 2006a, b). A 'side effect' is limitation of 5-HT synthesis, particularly in the CNS, since tryptophan competes with similar amino acids at the uptake pump across the blood-brain barrier. It has been shown that the resulting serotonin deficit in the brain is related to a central depression that has also been described as 'sickness behavior', since it is commonly associated with infections, and particularly chronic inflammatory problems as well as autoimmune conditions (Russo *et al.*, 2003; Wirleitner *et al.*, 2003; Capuron and Miller, 2004; Spalletta *et al.*, 2006).

On the other hand, there are many indications that pro-inflammatory cytokines such as TNF $\alpha$ , IL-1 and IL-6 increase serotonin levels throughout the brain and also in the periphery. Dunn and others demonstrated increases in the 5-HT metabolite 5-HIAA throughout the brain following IL-1 injections (Dunn, 2006). Both TNF $\alpha$  and cytokine IL-1 activate the expression of SERT (Zhu *et al.*, 2006), and IL-6 increases peripheral serotonin levels in a rat model for pulmonary hypertension (Miyata *et al.*, 2001). Peripheral IL-6 injection leads to increased striatal 5-HT levels (Zhang *et al.*, 2001). Treatment of colonic mucosa cells *in vitro* with pro-inflammatory cytokines, including TNF $\alpha$ , reduced 5-HT function (Foley *et al.*, 2007). Moreover, a selective serotonin increase was observed in frontal cortical regions following infectious immune-stimulation in the lungs (Lowry *et al.*, 2007). Thus, 5-HT levels appear to be modulated in a push-pull fashion by different types of cytokines and peripheral immune responses.

The pro-inflammatory cytokines IL-6 and TNF $\alpha$ , along with macrophage inflammatory protein (MIP-1) and interferon- $\alpha$  (IF- $\alpha$ ), are also described as pyrogenes – substances that cause and modulate fever (Blatteis, 1990; Morrow *et al.*, 1996; Oka *et al.*, 2001). Fever represents an alteration of the body's temperature set-point, and occurs in response to both infectious and inflammatory processes, as well as to stress, particularly psychogenic stress (Blatteis, 1990; Morrow *et al.*, 1996; Oka *et al.*, 2001). The site for such temperature regulation appears to be the pre-optic area (POA) of the hypothalamus (Blatteis, 1990; Morrow *et al.*, 1996). Along with pro-inflammatory cytokines, serotonin itself is reported to modulate fever production via the POA (Blatteis, 1990). Thus, fever may

represent a state of increased serotonin availability in the brain. This could be meaningful within the context of observations that fever improves behavioral performance in children with ASD (Curran *et al.*, 2007).

### *Environmental modulators*

Another intriguing aspect of the 5-HT hypothesis for ASD is the susceptibility of the serotonergic system to environmental toxins. Environmental toxins such as organophosphates, organomercury compounds and polychlorinated biphenyls have long been known to alter brain development and cognitive behavior in animal models (Chang, 1984; Trask and Kosofsky, 2000; Faroon *et al.*, 2001; Ricceri *et al.*, 2003; Venerosi *et al.*, 2006; Timofeeva *et al.*, 2008), and recently have been implicated in the etiology of ASD (D'Amelio *et al.*, 2005; Cohly and Panja, 2005; Bello, 2007; Pessah *et al.*, 2008). Although many, particularly organophosphates, were originally linked to the disruption of other modulatory neurotransmitter pathways, substantial serotonergic effects are documented in the literature as well (Seegal *et al.*, 1986; Oudar *et al.*, 1989; Raulf and Konig, 1991; Morse *et al.*, 1996; Marcusson *et al.*, 2000; Mariussen and Fonnum, 2001; Khan and Thomas, 2004; Aldridge *et al.*, 2005a, b, c; Slotkin and Seidler, 2007).

Environmental stressors, ranging from psychosocial to traumatic, shape the development of serotonergic neurotransmission, and are in turn regulated by serotonergic innervation (Herrenkohl *et al.*, 1988; Peters, 1988; Ogawa *et al.*, 1994; Baumann *et al.*, 1998; Schneider *et al.*, 1998; Meaney *et al.*, 2000; Vazquez *et al.*, 2000; Carrasco and Van de Kar, 2003; Hayley *et al.*, 2005; Matsumoto *et al.*, 2005). For example, male rodent pups, maternally separated for periods of hours over the course of infancy, show significantly decreased 5-HT in hippocampus and frontal cortex (Resnicov and Nosenko, 1996; Vazquez *et al.*, 2000; Mathews *et al.*, 2001). At the same time, both 5-HT $_1$  and 5-HT $_{2A}$  receptors are up-regulated following such treatment (Vazquez *et al.*, 2000; Mathews *et al.*, 2001). Several experimental studies have now demonstrated that the effects of perinatal stress can become epigenetically hard-wired during brain development, and that the serotonergic innervation to the forebrain is instrumental in this process (Meaney *et al.*, 2000; Seckl and Meaney, 2004; Weaver *et al.*, 2004). A recent review describes a frontocortical-amygdala-dorsal raphe feedback loop involved in the serotonergic modulation of stress responsiveness in the adult (Holmes, 2008). It is presumably this circuitry that becomes epigenetically altered as a consequence of early developmental stress or trauma, as suggested by findings in mice with genetically or pharmacologically altered 5-HT $_1$ - and 5-HT $_{2A}$ -type receptor availability (Holmes, 2008).

*BDNF*

Towards the beginning of this chapter, we discussed basic research evidence for the morphogenetic role of serotonin in cortical network formation. A molecule that is well positioned to serve as an intermediary in this process is Brain Derived Nerve Growth Factor (BDNF). Altered BDNF levels have consistently been found in ASD. Most studies have been based on analyzing serum or blood levels, and both show significant increases (Miyazaki *et al.*, 2004; Connolly *et al.*, 2006; Nelson *et al.*, 2006; Nishimura *et al.*, 2007) or decreases (Hashimoto *et al.*, 2006; Katoh-Semba *et al.*, 2007) of BDNF in ASD. Recent assessments of normal developmental BDNF trajectories in blood show that BDNF protein is increased in childhood, and subsequently attenuates towards adult levels (Nelson *et al.*, 2006). Thus, reports of increased vs. decreased levels might depend on developmental age at the time of testing or, alternatively, the widely divergent methods employed to measure peripheral BDNF. In addition, BDNF levels are subject to diet, exercise, stress and neuroinflammation (Kerschensteiner *et al.*, 2003; Tabakman *et al.*, 2004; Ferris *et al.*, 2007; Araya *et al.*, 2008; Tang *et al.*, 2008), suggesting that these variables need to be considered, in addition to age and sex (Trajkovska *et al.*, 2007), when assessing patient cohorts.

BDNF is among a small group of CNS neurotrophins that are instrumental in regulating neuronal survival, differentiation and synapse formation, and are necessary for the plastic adjustment of the developing brain to the environmental cues as well as for normal cognitive function in the adult (Huang *et al.*, 1999; McAllister, 2001; Branchi *et al.*, 2004; Garoflos *et al.*, 2005a; Kuipers and Bramham, 2006; Gunstad *et al.*, 2008). Neurotrophins and their receptors are expressed in the neocortex and hippocampus (Cellerino and Maffei, 1996; Marty *et al.*, 1996; Huang *et al.*, 1999; Lein *et al.*, 2000; McAllister, 2002) and the patterns of neurotrophin expression are activity-dependent and regulated by sensory inputs, electrical activity and stimulation (Aloyz *et al.*, 1999; Huang *et al.*, 1999; Balkowiec and Katz, 2000; McAllister, 2001). BDNF and its receptor, *trkB*, are densely expressed on cortical and hippocampal neurons, and influence both axonal and dendritic growth in a highly neuron-specific and age-dependent manner (Huang *et al.*, 1999; Xu *et al.*, 2000; McAllister, 2001). The expression of the *trkB* receptor peaks in the first 2 weeks postnatally in rodents, near the peak age of synapse formation, but BDNF action on cortical plasticity continues into adulthood (McAllister, 2002; Gomes *et al.*, 2006; Kuipers and Bramham, 2006). With maturation, *trkB* becomes enriched at the site of glutamatergic synapses and is uniquely able to modulate experience-dependent plasticity in cortical areas (Gomes *et al.*, 2006). Based on this neurobiology, it is

somewhat surprising to find BDNF expression in serum and peripheral tissues. However, recent studies suggest an immune-modulatory role for BDNF (Kerschensteiner *et al.*, 2003; Schulte-Herbruggen *et al.*, 2007). Although neurotrophins have primarily been localized to neurons, subsets of cells from the immune system (e.g., macrophages, lymphocytes, mast cells) synthesize and produce neurotrophins and associated receptors in response to injury or inflammation (Kerschensteiner *et al.*, 1999; Tabakman *et al.*, 2004; Nassenstein *et al.*, 2005; Nockher and Renz, 2006). There are even indications that BDNF can be introduced to the brain by immune cells (Correale and Villa, 2004; Tabakman *et al.*, 2004).

BDNF and serotonin show reciprocal regulation and respond to the same environmental factors (Branchi *et al.*, 2004; Mattson *et al.*, 2004). For example, mice heterozygous for BDNF expression (BDNF<sup>+/-</sup>) display premature, age-associated loss in forebrain serotonergic innervation (Lyons *et al.*, 1999) and impaired SERT function (Daws *et al.*, 2007). Localized increases in BDNF expression promote 5-HT fiber sprouting after injury (Mamounas *et al.*, 1995; Grider *et al.*, 2005). In turn, 5-HT depletion, via inhibition of synthesis, is accompanied by decreases in BDNF levels in the mature hippocampus (Zetterstrom *et al.*, 1999). During brain development, factors such as perinatal stress or environmental enrichment lead to long-term alterations in BDNF expression in brain and blood plasma (Vaidya *et al.*, 1997; Branchi *et al.*, 2004; Fumagalli *et al.*, 2004; Roceri *et al.*, 2004; Garoflos *et al.*, 2005b). In rat, maternal infection can cause long-term increases in BDNF within the cerebral cortex and other brain areas (Gilmore *et al.*, 2003). Interestingly, within the context of gender disparity in ASD and sex differences observed in our mouse model, there are indications of differential BDNF regulation in males and females (Cavus and Duman, 2003; Szapacs *et al.*, 2004; Sohrabji and Lewis, 2006).

### **A conceptual framework for the etiology of ASD behavioral endophenotypes**

As indicated in the introduction, the particular focus of this chapter is the role of serotonin in the cortical pathology of ASD, largely because this is an area where a richness of basic research can inform translational hypotheses. We do not regard ASD as a purely cortical brain disorder, as there are well-known neuropathologies in the cerebellum and brainstem, among other regions (Kemper and Bauman, 1998; Trotter *et al.*, 1999; Keller and Persico, 2003; Courchesne *et al.*, 2005; Santangelo and Tsatsanis, 2005). Some brainstem neuropathologies (Rodier *et al.*, 1996; Courchesne, 1997; Bailey *et al.*, 1998), along with

alterations in segmentation genes in ASD (Hashimoto *et al.*, 1992; Ingram *et al.*, 2000; Conciatori *et al.*, 2004; Tischfield *et al.*, 2005), are actually consistent with serotonergic abnormalities. The serotonergic neurons in the raphe nuclei form within regions of the brainstem reported to be affected in ASD (Lauder *et al.*, 1982; Wallace *et al.*, 1982). Moreover, the cerebellum receives a modulatory 5-HT innervation (Dieudonne, 2001).

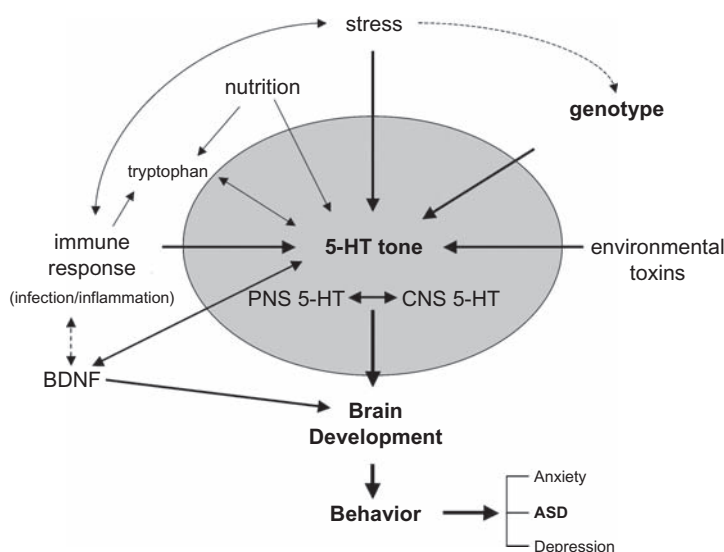

We do hypothesize that most behavioral indicators of ASD are the consequence of late developmental and early postnatal alterations in brain development and plasticity. Moreover, data from our animal model suggest that cerebral cortical network formation can be implicated in substantial aspects of the behavioral pathologies. This view has important therapeutic implications for designing postnatal interventions that may be effective in substantially improving behavioral and cognitive outcomes in ASD (see Bethea and Sikich, 2007). This has to some extent already been borne out by the effectiveness of some early behavioral interventions (Landa, 2007; Dawson, 2008).

With many others, we are proponents of the theory that ASD is not a single disorder, but in fact a spectrum of disorders with a similar 'final common pathway' of altered brain network assembly and fine-tuning. The hypothesis that serotonergic tone may be a major factor in this 'final common pathway' is compatible with the available data as reviewed in this chapter. Figure 3 illustrates the pervasive role of serotonergic tone in brain and body homeostasis and development.

In essence, there are two different serotonergic systems, one each in the PNS and CNS, but these two 'branches'

are linked within an intricate web of mutually regulatory mechanisms. It is most significant that the main difference between the PNS and CNS 'branches' is the location of 5-HT synthesis and the synthesizing enzyme, but beyond that most molecular components of signal transduction (receptors, uptake pumps) are shared. Thus, a genetic or environmental insult to the function of most gene products involved in serotonergic communication will affect both peripheral and central functions. At the same time, dysregulation of just the PNS serotonergic system by way of inflammatory or infectious insults, or via genetic deficits in aspects of immune response or digestive function, can derail central serotonergic innervation and modulation of brain development. Research has only scratched the surface of identifying the molecular regulators, such as neurotrophins (BDNF) or transcription factors (Pet-1, homebox genes), that might be intermediates in the CNS serotonergic modulation of brain development. Likewise, the study of neuro-immune modulation of brain morphogenesis has just begun. It is not hard to imagine, with this scenario, how dozens or even hundreds of different genes could be implicated in derailing serotonergic tone. A recent review illustrates, on the basis of genetically engineered mice for various serotonergic genes, the plethora of epistatic and/or additive effects that might result from just combining a handful of altered genes (Murphy *et al.*, 2003).

It would make sense that altered function of multiple genes or gene-products is necessary to imbalance serotonergic homeostasis/neurotransmission sufficiently to generate a disease state. In some instances, inherited

**Figure 3** Summary diagram. This diagram shows the many influences on serotonin tone, which is the result of interactions between serotonergic systems in the peripheral (PNS) and central (CNS) nervous systems. The thickness of the lines denotes the estimated degree of influence, based on the literature reviewed in this chapter. Dotted lines represent influences that are understood less.

multi-gene vulnerabilities might be sufficient to precipitate ASD; in the majority of instances, multiple gene vulnerabilities might require one or more environmental factors, such as stress, infection or toxicants, to result in a functional breakdown and ASD. Furthermore, the severity of imbalances and developmental timing of a serotonergic dysfunction might determine whether the resulting disease state will resemble full-blown autism, Asperger's syndrome, anxiety disorder, or perhaps even depression or bipolar illness. Additional phenotype differences are the likely consequence of 5-HT imbalances interacting with other background genes.

How, in turn, do we envision a CNS serotonin imbalance to affect cortical and perhaps also limbic and cerebellar network formation? As the data in the first section of this review show, the cortical serotonergic innervation is instrumental in shaping afferent thalamo-cortical fiber ingrowth. It also influences the ability of the arriving fibers to appropriately activate their cortical targets and subsequently reorganize in a plastic way to accommodate afferent sensory input in the process of cortical map formation. The effects of the serotonergic innervation to frontal cortical association areas has not received much scrutiny in animal models, likely because in animals such as mouse, rat and cat it presents a much harder paradigm to study. Unlike parietal and occipital sensory cortex, frontal association cortex receives its input predominantly from other cortical areas (Goldman and Nauta, 1977; Jacobson and Trojanowski, 1977). Yet, as the data reviewed in the second section of this chapter show, frontal cortex undergoes a period of synaptic development, followed by pruning and fine-tuning of connectivity that is likely to benefit from serotonergic modulation in similar ways as primary sensory cortical areas. Moreover, altered minicolumns are observed in the frontal cortex as well as in parietal areas (Casanova *et al.*, 2002). Finally, the frontal cortical circuitry is intimately linked to limbic system control, and constitutes a network that is tightly controlled by serotonergic innervation in the mature brain (Holmes, 2008). Thus, we hypothesize that altered serotonergic tone in development can alter proper cortical network formation in both sensory and motor areas, as well as in association areas of cortex. Altering sensorimotor network function, in itself, would provide frontal association cortex with 'scrambled' information about the peripheral world, and impede both executive functions and proper social-emotional responses. Altered maturation of associative cortical networks, on top of that, would surely exacerbate the effects. The extent of effects on cortical regions may be related to the timing of serotonergic inputs. As reviewed above, CNS serotonergic abnormalities in ASD appear to be restricted to the early postnatal years and attenuate later. Since frontal cortex

matures much later than the primary sensory and motor areas, it might be spared the brunt of the central serotonergic imbalances. However, PNS effects on serotonergic tone, including neuro-inflammatory events, could alter this time-line.

The molecular mechanism involved in serotonergic modulation of cortical network formation, without doubt, involves both glutamatergic and GABA-ergic synaptic connections. Thalamocortical afferents use glutamate as their excitatory neurotransmitter (Salt and Hill, 1983). Experimental evidence shows that glutamate receptors (GluRs) play roles in the activity-dependent refinement of synaptic connectivity (Constantine-Paton and Law, 1982; Daw *et al.*, 1993; Fox and Daw, 1993). GluRs are classified broadly into two groups: ionotropic sites, linked to ion channels; and metabotropic sites, linked to second messengers. The ionotropic sites include those activated by the exogenous agonists *N*-methyl-D-aspartate (NMDA), amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) and kainate (KA). NMDA receptors influence both the retraction of incorrectly placed axon arbors and synapses and the elaboration of correctly positioned terminals, and are instrumental in learning and memory functions in immature as well as mature cortex (Daw *et al.*, 1993; Fox and Daw, 1993; Rocha and Sur, 1995; Bear, 1996; Iwasato *et al.*, 1997). In addition, metabotropic glutamate receptors are involved in fine-tuning synaptic connectivity (Anwyl, 1991; Reid and Romano, 2001; Catania *et al.*, 2007).

Although they are excitatory during early cortical development, GABAergic interneurons in cortex eventually serve inhibitory functions and are essential in receptive field and thus proper map formation (Herlenius and Lagercrantz, 2001). Several different recent papers have pursued the hypothesis that ASD might be a disease of reduced GABAergic inhibition (Rubenstein and Merzenich, 2003; Minshew and Williams, 2007). This has partially been based on the concept that the morphological changes associated with minicolumns in ASD might suggest reductions in GABAergic neurons (Minshew and Williams, 2007). Additional support for this argument has been provided by the occurrence of seizures in approximately one-third of ASD cases (Rubenstein and Merzenich, 2003).

Our concept is compatible with both these theoretical frameworks. Altered cortical network formation, such as would occur with altered serotonergic modulatory tone, creates 'noisy' connectivity by altering both excitatory and inhibitory synapses. In keeping with the idea that brainstem modulators to cortex, including serotonergic mechanisms, affect signal-to-noise ratios in their cortical targets, these afferents would be unable properly to 'drive' postsynaptic cortical neurons, whether these are excitatory

(glutamatergic) or GABA-ergic (Rauschecker, 1991b; Herlenius and Lagercrantz, 2001; Gu, 2002; Siri *et al.*, 2007). This idea is supported by the literature reviewed in the first section of this chapter, concerning serotonergic modulation of thalamocortical glutamatergic tone as well as direct modulation of cortical neuronal activity. Activity regulated neurotrophins, such as BDNF, would clearly play a prominent role in mediating these modulatory events. The likely result would be an initial overproduction of weak synapses in cortex, followed by a later phase of pruning that is somewhat haphazard rather than selective for the most appropriately 'tuned' connections. Such a cortex would be more vulnerable to seizure activity. This scenario also is compatible with the increased cortical volume early in development that is followed by decreased connections later, as indicated by diffusion tensor imaging studies (see Minshew and Williams, 2007). As discussed above, serotonergic disruptions are also compatible with the findings of early brainstem changes and the well-established alterations in cerebellar development. In some cases of ASD, brainstem abnormalities, whether the consequence of genetic or toxic influences, may be the primary deficit. Segmentation genes such as *Engrailed* [Eng] alter the generation and/or location of dorsal raphe serotonergic neurons along with cerebellar histogenesis (Gharani *et al.*, 2004; Cheh *et al.*, 2006). Alternatively, the cerebellum might be directly impacted by an abnormal serotonergic innervation. While the serotonergic innervation to the cerebellum is very well characterized, little is known about its developmental function in mammals.

## Conclusion

In this chapter we have presented a review of a large body of basic science and ASD-related literature that supports the idea that altered serotonergic homeostasis in the CNS and PNS may be prominently involved in the pathogenesis of ASD. In the CNS, experimental animal models have provided some proof of concept for this. However, investigations into the role of serotonin in immune regulation, and particularly neuroimmune regulation, are very much in their infancy. A unified hypothesis such as proposed here could provide an avenue towards early identification of biomarkers as well as therapeutic strategies. We hope to have provided an impetus for new investigations into a 'serotonergic hypothesis' for ASD.

# Serotonin in Panic and Anxiety Disorders

Francisco S. Guimarães<sup>\*,1</sup>, Hélio Zangrossi Jr.<sup>1</sup>, Cristina M. Del Ben<sup>2</sup> and Frederico G. Graeff<sup>2</sup>

<sup>1</sup>*Department of Pharmacology, Faculdade de Medicina de Ribeirão Preto, Universidade de São Paulo, Ribeirão Preto, Brazil*

<sup>2</sup>*Department of Neuroscience and Behavioral Sciences, Hospital das Clínicas da Faculdade de Medicina de Ribeirão Preto, Universidade de São Paulo, Ribeirão Preto, Brazil*

**Abstract:** Selective serotonin reuptake inhibitors (SSRIs) are largely used to treat several anxiety disorders. Nevertheless, despite being the focus of intensive research interest over the past 35 years, the precise role of serotonin (5-HT) in anxiety remains incompletely understood. More recently, it has been suggested that SSRI effects depend on facilitation of 5-HT-mediated neurotransmission in two parallel, longitudinally organized defensive systems that would be distinctly engaged by different threatening stimuli. 5-HT would play a dual role in these systems, facilitating anxiety but inhibiting panic. As reviewed in the present chapter, this proposal has received support from clinical and basic studies. Recent evidence has also suggested that disturbances in 5-HT-mediated neurotransmission in these systems could be involved in the genesis of pathological anxiety in humans, particularly panic disorder.

**Keywords:** serotonin, anxiety, panic, anxiolytics, antidepressants, periaqueductal gray, amygdala, hippocampus, raphe nuclei, prefrontal cortex.

## Introduction

The first suggestions regarding the role of serotonin (5-HT) in anxiety were based on experimental evidence obtained in laboratory animals. Among the early animal models of anxiety, the so-called punishment or conflict test had shown the highest predictive value for the clinical response in anxious patients for the drugs available in the 1960s and 1970s, mainly barbiturates and benzodiazepines. Typically, drugs that relieved anxiety in humans were able to release behavior maintained by response-contingent presentation of a reinforcer (such as food or water) which was also suppressed by the delivery of an aversive stimulus (such as electric shock) following the same response. In this way, an approach-avoidance conflict is generated, the avoidance tendency being decreased by anxiolytics.

As a consequence, the observation that drugs that acted on 5-HT changed punished behavior has implicated this neurotransmitter in anxiety. Using the rat conflict test designed by Geller and Seifter (1960), Robichaud and Sledge (1969) showed that decreasing brain 5-HT by injecting the selective inhibitor of 5-HT synthesis para-chlorophenylalanine (PCPA) releases bar-pressing simultaneously rewarded by sweetened milk presentation and punished by

foot-shock. In the same direction, Graeff and Schoenfeld (1970) reported that the non-selective 5-HT receptor antagonists methysergide and bromolysergic acid (BOL) increase key-pecking rates maintained by food presentation, concurrently suppressed by response-contingent electric shocks, whereas the receptor agonist  $\alpha$ -methyltryptamine has the opposite effect. On the basis of these results, they suggested that tryptaminergic mechanisms in the brain mediate the response suppression determined by punishment.

Shortly thereafter, Wise *et al.* (1972) showed that the benzodiazepine anxiolytic oxazepam reduces 5-HT turnover in the rat midbrain, at the same dose that released punished responding in the Geller-Seifter conflict test. Since it was already known that midbrain raphe nuclei contained the cell bodies of 5-HT neurons that project to the forebrain and brainstem, they proposed that ascending 5-HT pathways would mediate the effects of punishment by acting on structures that suppress ongoing behavior localized in both the forebrain and in the periaqueductal gray matter (PAG) of the midbrain. Benzodiazepine anxiolytics would reduce anxiety by decreasing 5-HT release in these brain areas. Therefore, in the theoretical model designed by Wise *et al.* (1972), 5-HT is supposed to enhance anxiety by acting both in the forebrain and in the PAG (see Figure 1).

The first tenet of the above hypothesis was supported by the results obtained by Tye *et al.* (1977) with the

5-HT was proposed by Wise *et al.* (1972) to mediate the effects of punishment by acting on structures that suppress ongoing behavior localized in both the forebrain and in the periaqueductal gray matter (PAG) of the midbrain. Benzodiazepine anxiolytics would reduce anxiety by decreasing 5-HT release in these brain areas. +, facilitation. neurotoxin 5,7-dihydroxytryptamine (5,7-DHT), which selectively damages 5-HT neurons. Their results showed that microinjection of 5,7-DHT into the ventromedial tegmentum of the rat midbrain causes 70 percent depletion of cortical 5-HT, indicating a major lesion of ascending 5-HT pathways, and prevents the acquisition of response suppression induced by foot-shock in a modified Geller-Seifter procedure. In the same vein, Schoenfeld (1976) reported that the hallucinogens lysergic acid diethylamide (LSD) and mescaline release punished licking in the rat, and suggested that this effect may be due to decreased activity of ascending serotonergic neurons. As complementary evidence, Graeff and Silveira Filho (1978) found that electrical stimulation of the median raphe nucleus (MRN) inhibits ongoing lever-pressing behavior maintained by a variable-interval schedule of water presentation. In addition, such brain stimulation induces defecation, urination, piloerection, teeth clattering and exophthalmos, mimicking the effect of a conditioned aversive stimulus in the conditioned suppression and conditioned emotional response procedures (Estes and Skinner, 1941; Millenson and Leslie, 1974). Moreover, pre-treatment with PCPA was shown to reduce the effect of MRN electrical stimulation, suggesting a 5-HT mediation of the response suppression. Since MRN 5-HT neurons project mainly to the dorsal hippocampus (Azmitia and Segal, 1978), the latter results agree with Gray's (1982) proposal that anxiety is due to activation of the septo-hippocampal system. In addition to the septo-hippocampal system, 5-HT may

also act in the amygdala to mediate the effects of punishment. For instance, microinjection of 5-HT antagonists into the basolateral amygdala was shown to release water licking suppressed by electric shock punishment (Petersen and Scheel-Krüger, 1984). These results add to a large body of evidence implicating the amygdala in the learning and expression of conditioned fear and anxiety (Davis, 1992; LeDoux, 1993).

In summary, these initial studies clearly suggested that facilitation of 5-HT-mediated neurotransmission facilitates anxiety. As will be seen below, a large body of clinical and animal studies, although clearly implicating 5-HT in the neurobiology of anxiety, indicates that this classical view can not be sustained any longer.

### 5-HT related drugs and the treatment of anxiety disorders

The clinical link between serotonin and anxiety could be traced back to the key observation by Klein and Flink (1962) that chronic treatment with imipramine has a beneficial effect in panic patients. Although it was subsequently recognized that imipramine is also effective in generalized anxiety disorder (GAD) (Kahn *et al.*, 1986), this initial finding was critical for the recognition of panic as a distinct anxiety disorder. Imipramine, however, is able to block the reuptake of both noradrenaline and serotonin, and the involvement of the latter neurotransmitter in its anxiolytic effects was not immediately recognized. The link between 5-HT and clinical anxiolytic effects became clear during the late 1970s–1980s, with the clinical introduction of buspirone, a partial 5-HT<sub>1A</sub> receptor agonist effective in GAD patients (Goldberg and Finnerty, 1979), and the selective serotonin reuptake inhibitors (SSRIs). The latter group, being usually well tolerated and having a broad spectrum anxiolytic efficacy, is nowadays considered as first-line pharmacological treatment for several anxiety disorders, including GAD, panic (PD), social anxiety disorder (SAD) and post-traumatic stress disorder (PTSD) (Baldwin *et al.*, 2005).

Although other 5-HT-related compounds have also been tested in patients with anxiety disorders, results are far from encouraging. For example, whereas ritanserin, a 5-HT<sub>2A/2C</sub> receptor antagonist, seems to be effective in GAD patients (Ceulemans *et al.*, 1985), it has no effect or even aggravates PD (den Boer and Westenberg, 1990). Mixed results have also been observed with 5-HT<sub>3</sub> receptor antagonists (Lecrubier *et al.*, 1999; Romach *et al.*, 1998; Hewlett *et al.*, 2003) and 5-HT<sub>1A</sub> agonists (van Vliet *et al.*, 1996). Open studies have also suggested that d-fenfluramine, a 5-HT releaser, could improve panic patients resistant to traditional treatments (Solyom, 1994;

Hetem, 1996). This drug was, however, withdrawn from the market due to side-effects.

### How do SSRIs and buspirone work?

The acute pharmacological effects of SSRIs and buspirone are well-known. However, it needs at least 2–3 weeks before the beneficial effects of these compounds become evident in patients with anxiety disorders. Several proposals have been made to try to explain the delay in therapeutic effects. Electrophysiological studies indicate that repeated administration of SSRIs or buspirone can attenuate the function of inhibitory 5-HT<sub>1A</sub> autosomic receptors, without affecting 5-HT<sub>1A</sub> postsynaptic function (Blier and Abbott, 2001; Blier and Ward, 2003). As a consequence, there would be an increased 5-HT-mediated neurotransmission in projection areas. Although imipramine does not seem to share this effect with SSRIs, it can sensitize 5-HT<sub>1A</sub> postsynaptic receptors located in areas such as the hippocampus and amygdala (Gordon and Hen, 2004). Since buspirone is also a partial 5-HT<sub>1A</sub> agonist, stimulation of these receptors located postsynaptically in limbic areas has been proposed to mediate at least part of the anxiolytic effects of these drugs (Gordon and Hen, 2004; Guimarães *et al.*, 2008). Postsynaptic changes in 5-HT<sub>2</sub> receptors could also be involved. Long-term treatment with several classes of antidepressants desensitizes 5-HT<sub>2C</sub> receptors in limbic areas (Millan, 2006a). These receptors have been proposed to exert a negative action over mood that would be opposed by postsynaptic 5-HT<sub>1A</sub> receptors (Millan, 2006b). Therefore, antidepressants would cause anxiolytic effects by both down-regulating 5-HT<sub>2C</sub> and facilitating effects mediated by postsynaptic 5-HT<sub>1A</sub> receptors (Millan, 2006a, b). Since 5-HT<sub>2C</sub> receptors may be constitutively active, whereas stimulation of postsynaptic 5-HT<sub>1A</sub> receptors requires spontaneous release of 5-HT, a general decrease in 5-HT-mediated neurotransmission would shift the balance towards 5-HT<sub>2C</sub>-mediated anxiogenic effects (Millan, 2006b). In addition to 5-HT<sub>2C</sub>, down-regulation of 5-HT<sub>2A</sub>-mediated neurotransmission by repeated treatment with buspirone or antidepressants could also be involved in the anxiolytic effects of these drugs (Millan, 2003; Weisstaub *et al.*, 2006).

A strong argument relating 5-HT to the anxiolytic effects of SSRIs came from controlled clinical trials using tryptophan depletion to decrease brain 5-HT level. These studies showed that the therapeutic effect of SSRIs is reverted by 5-HT depletion in PD and SAD (Bell *et al.*, 2002; Argyropoulos *et al.*, 2004). The 5-HT precursor 5-hydroxytryptophan (5-HTP), on the other hand, was able to attenuate panic symptoms induced by CCK4 or CO<sub>2</sub> in PD patients (Schrüers *et al.*, 2002; Maron *et al.*,

2004a), whereas tryptophan depletion and metergoline facilitated these symptoms (Ben-Zion *et al.*, 1999; Miller *et al.*, 2000). Results regarding OCD are not so clear. Only mood, but not OCD, symptoms were sensitive to tryptophan depletion. This suggests that the therapeutic effects of SSRIs over the latter cluster of symptoms do not depend on short-term availability of 5-HT (Kulz *et al.*, 2007).

In addition to these effects, long-term treatment with SSRIs, probably by facilitating 5-HT-mediated neurotransmission, has been shown to induce several plastic changes and increase neurogenesis in the hippocampus (Santarelli *et al.*, 2003). Chronic treatment with these compounds facilitates neurogenesis in the dentate gyrus, probably by activation of hippocampal 5-HT<sub>1A</sub> receptors. Hippocampal neurogenesis inhibition has been shown to prevent anxiolytic effects of these drugs in mice (Santarelli *et al.*, 2003). In addition to neurogenesis, hippocampal levels of the brain-derived neurotrophic factor (BDNF) have also been related to stress-induced behavioral changes. Studies investigating the effects of SSRIs on these levels have produced conflicting results (Greenwood *et al.*, 2007). However, the behavioral effects of chronically administered SSRIs were shown to depend on BDNF signaling in some studies (Saarelainen *et al.*, 2003). Despite these results, the acute reappearance of anxiety symptoms in SSRI-treated patients induced by tryptophan depletion (see above) indicates that caution must be exerted when considering these neuroplastic proposals as unitary explanations of the long-term effects of these drugs.

### Are anxiety disorders caused by disturbances in 5-HT-mediated neurotransmission?

Although the therapeutic efficacy of 5-HT-interacting compounds clearly points to an involvement of this neurotransmitter in anxiety disorders (Gordon and Hen, 2004), the question remains of whether these disorders are caused by disturbances in 5-HT-mediated neurotransmission.

Impairment of 5-HT<sub>1A</sub>-mediated neurotransmission in PD has been shown by several neuroendocrine studies (Lesch *et al.*, 1992; Broocks *et al.*, 2000; Mortimore and Anderson, 2000). These studies also suggest an increased 5-HT<sub>2C</sub> sensitivity in PD and post-traumatic stress disorder (PTSD), but a decreased sensitivity in OCD. Since blunted responses to the 5-HT releaser d-fenfluramine have been found in patients with PD and OCD, the increased sensitivity of 5-HT<sub>2C</sub> receptors in these disorders may be reflecting a compensatory up-regulation of 5-HT<sub>2C</sub> receptors due to a decrease in 5-HT neurotransmission (Guimarães *et al.*, 2008).

Genetic association studies also suggest that gene variants of the 5-HT system may contribute to anxiety susceptibility, particularly in PD (for review, see Maron and Shlik, 2006). Neuroimaging studies have not only supported this proposal but also been helpful in elucidating genetic influences on these disorders (Hariri *et al.*, 2005; Iidaka *et al.*, 2005).

An inverse correlation has been found between 5-HT<sub>1A</sub> binding and anxiety in healthy subjects and in patients with other neuropsychiatric disorders (Tauscher *et al.*, 2001; Savic *et al.*, 2004; Yasuno *et al.*, 2004). There is also a report of association between a single polymorphism in the regulatory region of the 5-HT<sub>3</sub> gene and greater reactivity in the amygdala and in the dorsal and medial PFC (Iidaka *et al.*, 2005). In patients with PD, fewer 5-HT<sub>1A</sub> receptors in the forebrain and raphe nuclei have been reported (Neumeister *et al.*, 2004; Nash *et al.*, 2008). A reduction of these receptors in limbic areas, particularly the amygdala, has also been shown in patients with SAD (Lanzenberger *et al.*, 2007), but not in patients with PTSD or GAD (Bonne *et al.*, 2005). In these patients, successful treatment with SSRIs antagonized activity changes during symptom provocation in the insula, and in prefrontal and inferior frontal cortices, suggesting the involvement of 5-HT (Fernandez *et al.*, 2001; Hoehn-Saric *et al.*, 2004). This same treatment has been shown to attenuate the increased activation of the anterolateral orbitofrontal cortex, caudate nucleus, thalamus and temporal regions in OCD patients (Carey *et al.*, 2004).

In addition to 5-HT receptors, several studies have investigated changes in the serotonin transporter (5-HTT). An increased 5-HTT binding has been reported in patients with GAD (van der Wee *et al.*, 2008), but an inverse correlation between 5-HTT binding and anxiety has also been reported (Maron *et al.*, 2004b). The presence of one or two copies of the short allele of the 5-HTT promoter predicts greater amygdala neuronal activity in response to fearful and angry facial expressions, compared with individuals homozygous for the long allele, suggesting a bias toward increased reactivity to stressful life experiences (Hariri *et al.*, 2005). However, studies comparing the presence of the short allele in anxiety disorders, such as OCD or GAD, have produced mainly negative results (Hesse *et al.*, 2004; Maron *et al.*, 2004b). Nevertheless, SAD patients with one or two copies of the short allele in the promoter region of the 5-HTT gene show increased anxiety-related traits, state anxiety, and enhanced right amygdala responding to anxiety provocation (Furmark *et al.*, 2004). Studies with PD patients have not found an association between the presence of polymorphisms in the 5-HTT promoter gene and the disorder (Blaya *et al.*, 2007; Strug *et al.*, 2008). However, an association between a polymorphism in the serotonin transporter gene and PD has been reported (Strug *et al.*, 2008).

Another point to be considered in these studies is that although several results support the presence of an association between changes in 5-HTT expression and emotional processing in the amygdala, the functional consequences of these changes on 5-HT-mediated neurotransmission are still not clear. A decrease in the expression of 5-HTT would, theoretically, increase synaptic 5-HT. There is evidence, however, that this polymorphism is associated with blunted 5-HT function (Reist *et al.*, 2001). Moreover, it is probable that this genetic trait interferes with neuronal development, causing long-term effects that go far beyond a simple change in 5-HT availability (see below).

Recent studies have also focused on the brain-specific tryptophan hydroxylase-2 (TPH2) gene, the rate-limiting enzyme in 5-HT synthesis. Although no association between polymorphisms in this gene and PD was found (Maron and Shlik, 2006), some polymorphisms have been shown to modulate amygdala responsiveness to emotional arousal. In addition, there is an additive effect on emotional processing in individuals carrying the combination of the T variant of TPH2 with the short variant (l/l) of the serotonin transporter gene (5-HTT) (Canli *et al.*, 2008).

In conclusion, several results from the clinical literature indicate that anxiety disorders, particularly PD, are associated with disturbances of 5-HT-mediated neurotransmission. How these disturbances bring about the complex and sometimes distinct symptomatology found in these disorders is still unclear. Therefore, data from studies with laboratory animals could bring a valuable help.

### **The dual role of 5-HT in anxiety: the Deakin and Graeff theory**

The complexity of the 5-HT system greatly contributes to the difficulty in understanding its role in anxiety. 5-HT can act on more than 14 receptor subtypes, located either pre- or postsynaptically, and in some cases in both locations. Moreover, their activation could produce opposite effects (Hoyer *et al.*, 2002). In addition to this intricate neurochemistry, the system also has a complex neuroanatomy. The widespread distribution of 5-HT fibers in the forebrain comes from two distinct raphe nuclei, the dorsal and median raphe nuclei (DRN and MRN, respectively). These nuclei innervate partially distinct structures (Pazos and Palacios, 1985; Barnes and Sharp, 1999; Hensler, 2006) and may present a high degree of heterogeneity (Clark *et al.*, 2006). For example, it has recently been shown that the projections to cortical and limbic structures arise from neurons located in a specific part of the caudal DRN that is particularly sensitive to stressful stimuli (for review, see Lowry *et al.*, 2005).

Studies with animal models of anxiety can potentially overcome some limitations of clinical investigations, and have been extensively used to investigate the role of 5-HT in anxiety (for comprehensive reviews, see Griebel, 1995; Blanchard *et al.*, 2003; Bourin and Hascoet, 2003; Millan, 2003; Olivier *et al.*, 2003; Prut and Belzung, 2003; Sanchez, 2003). Although the evidence reviewed so far using these models supports the hypothesis that 5-HT enhances anxiety by acting upon forebrain limbic structures, contrary results have been obtained in the PAG. Electrical stimulation of the dorsal PAG in laboratory animals induces defensive reactions, such as vigorous flight or defensive aggression (Hunsperger, 1956). These defense strategies are expressed in natural conditions when a predator is very close to or in direct contact with the prey (Blanchard *et al.*, 2001). Testifying to the aversive character of such stimulation, laboratory animals easily learn to switch off electrical stimulation of the dorsal PAG (Delgado *et al.*, 1954; Hunsperger, 1956). According to the above theoretical model, 5-HT is expected to facilitate such escape behavior. However, reported results with a procedure in which rats are trained to lever-press in order to decrease the intensity of dorsal PAG electrical stimulation suggest the opposite action. Indeed, using this decremental escape procedure, Kiser and coworkers showed that PCPA markedly increased the rate of bar-pressing (Kiser and Lebovitz, 1975; Kiser *et al.*, 1978a). Further results have shown that the precursor of 5-HT synthesis 5-hydroxytryptophan (5-HTP) reduces the same bar-pressing, and that the 5-HT reuptake inhibitor clomipramine has the same effect (Kiser *et al.*, 1978b). Finally, electrical stimulation of the dorsal raphe nucleus (DRN), which sends 5-HT nerve fibers to the PAG, has also been reported to depress responding (Kiser *et al.*, 1980). Together, these results show that manipulations that increase 5-HT activity in the dorsal PAG have an anti-aversive effect, whereas 5-HT depletion results in facilitation of escape from PAG electrical stimulation.

Further supporting an inhibitory function of 5-HT on aversion generated in the dorsal PAG, Schenberg and Graeff (1978) have shown that the 5-HT receptor antagonists cyproheptadine and methysergide decrease responding that switches off electrical stimulation of the dorsal PAG, whereas non-sedative doses of the benzodiazepine chlordiazepoxide facilitate switch-off responding (Schenberg and Graeff, 1978). Such opposing effects of a benzodiazepine anxiolytic and the 5-HT antagonist contrast with the similar anti-punishment effects of the two classes of drugs verified in conflict tests. Furthermore, using electrical stimulation of the dorsal PAG as a punishing stimulus, Morato de Carvalho and de Aguiar, (1981) have shown that, as expected, the anxiolytics chlordiazepoxide and pentobarbital released responding

maintained by water reinforcement, suppressed by the response-contingent delivery of electrical stimuli in the dorsal PAG. In contrast, the 5-HT receptor antagonist cyproheptadine did not increase punished responding at doses that had been shown to markedly release behavior punished by foot-shock (Graeff, 1974), and methysergide was also ineffective.

To explore the function of 5-HT in the PAG more directly, rats bearing a chemitrode – thus allowing microinjection of drugs associated with electrical stimulation – implanted into the dorsal PAG were placed inside a shuttle box, and the intensity of a sinusoidal current was gradually increased until the rat ran towards the opposite compartment of the shuttle box. This response was made to switch off the brain stimulation. The same procedure was repeated three times to determine the basal aversive threshold. Soon after, a drug microinjection was administered and 10 minutes later the aversive threshold was determined again. The difference between the magnitude of the post-drug and that of the basal threshold measured the drug effect on aversion. In the first study with this method, conducted by Schütz *et al.* (1985), microinjection of 5-HT as well as of the 5-HT receptor agonist 5-methoxy-N,N-dimethyltryptamine (5-MeODMT) into the dorsal PAG raised the aversive threshold dose-dependently. Local pretreatment with the 5-HT receptor antagonists metergoline or ketanserin blocked the anti-aversive effect of 5-HT. Since ketanserin is a relatively selective 5-HT<sub>2A</sub>-receptor antagonist, these results suggest that 5-HT inhibits aversion in the dorsal PAG by stimulating such 5-HT receptor subtype. This view has been further supported by results showing that the 5-HT<sub>2A/2C</sub> agonist 2,5-dimethoxy-4-iodophenyl-2-aminopropane (DOI) increases the aversive threshold (Nogueira and Graeff, 1995). The latter study has also shown that the 5-HT<sub>1A</sub> agonists, 8-OH-DPAT and ipsapirone, have a similar effect, while the 5-HT<sub>2C</sub> preferential agonist 1-(m-chlorophenyl) piperazine (mCPP) was ineffective. Using chemical instead of electrical stimulation, Marsden and coworkers showed that microinjection of 5-HT<sub>1A</sub> agonists into the PAG attenuated running behavior induced by microinjection of an excitatory amino acid into the dorsal PAG; the selective 5-HT<sub>1A</sub>-receptor blocker WAY-100635 antagonized this effect, whereas the preferential 5-HT<sub>2C</sub>-receptor agonist mCPP facilitated running (Beckett *et al.*, 1992; Beckett and Marsden, 1997). Therefore, stimulation of either the 5-HT<sub>1A</sub> or the 5-HT<sub>2A</sub> receptor in the dorsal PAG seems to inhibit escape.

It is worth remarking that in the results reported by Schütz *et al.* (1985), microinjection of a selective inhibitor of 5-HT reuptake into the dorsal PAG not only potentiated the anti-aversive effect of the following administration of 5-HT, but also had an anti-aversive effect of its own. This implies

the existence of 5-HT nerve fibers in the dorsal PAG that are physiologically regulating defense. This view has been strengthened by further experimental evidence showing that blockade of presynaptic 5-HT<sub>1B</sub> receptors that inhibit 5-HT release with isamoltane, microinjected into the dorsal PAG, also has an anti-aversive effect, which is blocked by local pre-treatment with the 5-HT<sub>2</sub>-receptor blockers ketanserin and ritanserin (Nogueira and Graeff, 1991).

Interestingly, administration of 5-HT receptor antagonists alone into the dorsal PAG has no effect on the aversive threshold (Schütz *et al.*, 1985; Nogueira and Graeff, 1991). This finding contrasts with the major aversive effects caused by compounds like bicuculline, which block  $\gamma$ -aminobutyric acid type A (GABAA) receptors in the dorsal PAG (Brandão *et al.*, 1982). It may be concluded that while GABAergic terminals tonically inhibit the neurons of the dPAG that control defensive behavior, serotonergic fibers seem to exert a phasic inhibition. As a consequence, it has been suggested that the modulatory action of 5-HT would only appear under conditions, such as stressful situations, that engage 5-HT systems (Deakin and Graeff, 1991).

Overall, the results reviewed so far indicate that 5-HT facilitates inhibitory avoidance by acting on forebrain structures such as the septo-hippocampal system and the amygdala, while inhibiting escape in the dorsal PAG. The amygdala and the PAG, plus the medial hypothalamus, constitute a set of interrelated structures, often referred to as the brain defense system (BDS), which controls defensive strategies and elaborates the accompanying emotional and motivational states. Although the three components of the BDS would work together to generate different kinds of defensive behavior, each structure is likely to exert specific functions. In this regard, Fanselow (1991) has suggested that the amygdala synthesizes the stimulus input from the environment and then signals to the PAG the degree of threat that this represents to the organism, whereas the PAG is in charge of selecting, organizing and executing the appropriate behavioral and neurovegetative defensive reactions.

On the basis of the systematic study of anti-predator defense in wild rats, Blanchard and Blanchard (1988) formulated the concept of defense levels. Three such levels have been identified as a function of the threat being potential (uncertain), distal or proximal, each evoking a peculiar defense reaction. Thus, when danger is uncertain, like in novel environments, rats perform cautious exploration aimed at risk assessment; when the predator is perceived at a safe distance, tense and attentive immobility (freezing) ensues; and when the predator is near or in actual contact with the rat, the animal rapidly flees, whenever possible, or otherwise threatens or even attacks the predator defensively. Comparative studies led to the conclusion that these basic defense strategies can be found in other animals, including non-mammalian species

(Blanchard *et al.*, 2001). Attempts to relate each level of defense with critical brain structures and to particular emotions (e.g., Graeff, 1994) led to the suggestion that the septo-hippocampal system and the amygdala would be the key structures for risk-assessment behavior and inhibitory avoidance, the related emotion being anxiety. The septo-hippocampal system would provide the cognitive component of anxiety, while the affective component would be integrated in the amygdala (Gray and McNaughton, 2000). At the other extreme, the vigorous undirected flight elicited by proximal danger would be related to panic, the critical structure being the dorsal PAG. At the intermediate level of distal threat, well-directed escape related to fear would be elaborated by the medial hypothalamus. Concerning psychopathology, the first level of defense has been related to generalized anxiety disorder (GAD) and the third to panic disorder (PD), the second being implicated in specific phobias (Deakin and Graeff, 1991; Gray and McNaughton, 2000).

Both the amygdala and the PAG receive serotonergic input mainly from the DRN. The axons that project onto the amygdala follow the DRN-forebrain tract, while those that go to the PAG run via the DRN-periventricular tract (Azmitia and Segal, 1978). Most of the nerve fibers that originate in the DRN are thin and have small varicosities that make preferential contact with 5-HT<sub>2</sub> receptors (Mamounas *et al.*, 1991). Given this background, a working hypothesis has been conceived to reconcile the experimental evidence on the role of 5-HT in defense, reviewed above (Graeff, 1991). According to this view, activation of the DRN results in facilitation of defense strategies that are mainly integrated at the amygdala and other forebrain areas, such as risk assessment and inhibitory avoidance. At the same time, proximal defense reactions that are chiefly organized in the dorsal PAG, such as escape and fight, are inhibited. The adaptive function of this disposition would be to inhibit extreme defense patterns, like flight or fight, in situations where predatory threat is uncertain or far from the prey. In these circumstances, such reactions are inappropriate, because they enhance the probability of detection by the predator. Instead, more flexible, largely learned, responses are likely to lead to successful defense. This construct has been extended to psychopathology, relating inhibitory avoidance and risk assessment to GAD and proximal defense to PD (Deakin and Graeff, 1991, Figure 2).

### ***Experimental tests of the Deakin and Graeff theory: clinical studies***

Two experimental models of anxiety in humans have been used to test this theoretical model: the simulated

public-speaking (SPS) and the skin conductance response (CSCR) tests (review of Graeff *et al.*, 2003). The SPS test consists, basically, in the preparation and performance of a speech in front of a videocamera. During the procedure, the participant can see his or her own image on a TV screen, and anxiety and other subjective measures are taken before, during and after the speech. Since fear of speaking is highly prevalent and generates anxiety in healthy persons irrespective of trait anxiety level (Palma *et al.*, 1994), it is supposed to be a species-specific fear. Pharmacological studies have shown that benzodiazepines decrease anxiety – measured by the anxiety factor of the Visual Analog Mood Scale (VAMS) – before and after the speech, but do not attenuate the increase of VAMS anxiety during speech preparation or performance (speaking fear). In contrast, and in agreement with the predictions of Deakin and Graeff's proposal, drugs that facilitate 5-HT-mediated neurotransmission decrease, whereas drugs that impair 5-HT function increase, speaking fear (Graeff *et al.*, 2003).

The CSCR test consists of the presentation, through earphones, of 10 neutral tones (habituation phase), followed

by a neutral tone paired with loud white noise (acquisition phase) and then by the representation of 10 neutral tones (extinction phase). During the procedure, measures of skin conductance (level, SCL; response, SCR and spontaneous fluctuations, SF) are taken. Anxiolytic drugs, such as diazepam and the 5-HT<sub>1A</sub> partial agonist buspirone, impaired conditioning, while anxiogenic drugs, such as the 5-HT agonist methyl-chlorophenylpiperidine (mCPP) and the 5-HT releaser d-fenfluramine, tend to facilitate conditioning (Graeff *et al.*, 2003).

The pharmacological profile of the above experimental human tests has some similarities with the pharmacological response observed in clinical practice in patients with the diagnoses of anxiety disorders. The anxiolytic drugs diazepam and buspirone are effective in the treatment of GAD (Baldwin and Polkinghorn, 2005), but not of PD (Bakker *et al.*, 2005). Both drugs had an anxiolytic effect in the CSCR test, without decreasing speaking fear in the SPS test.

Some antidepressants largely used for the treatment of anxiety disorders have also been tested in these models of human experimental anxiety. The acute administration

**Figure 2** The dual role of 5-HT on defensive behaviors proposed by Deakin and Graeff (1991). By activating the dorsal raphe nucleus, threatening stimuli would facilitate defense strategies that are mainly integrated at the amygdala and other forebrain areas, such as risk assessment and inhibitory avoidance. At the same time, proximal defense reactions that are chiefly organized in the dorsal periaqueductal gray (dPAG), such as escape and fight, would be inhibited. In humans these strategies have been associated, respectively, with generalized anxiety (GAD) and with panic, phobias and social anxiety. +, facilitation; −, inhibition. Drawings modified from *The Rat Brain in Stereotaxic Coordinates – The New Coronal Set*, 5th edn, by George Paxinos and Charles Watson, 2005.

of clomipramine (Guimarães *et al.*, 1987) and nefazodone (Silva *et al.*, 2001) increased speaking fear in the SPS test, and this effect has been related to the worsening of anxiety symptoms frequently observed at the beginning of the treatment with antidepressants. It has been proposed that the fear-enhancing effect of a single dose of antidepressants in SPS is due to a lack of 5-HT inhibition of brain systems that generate panic attacks, likely to be localized in the dorsal PAG. Although some microdialysis studies in animals have shown increases in cortical extracellular 5-HT following acute SSRI administration (Moret and Bridley, 1996; David *et al.*, 2003; Felton *et al.*, 2003) others have shown a greater increase of extracellular 5-HT in the raphe nuclei than in the neocortex (Bel and Artigas, 1992). Therefore, it is possible that acute doses of antidepressants preferentially increase 5-HT concentration near the cell bodies of serotonergic neurons, reducing their firing rate due to the activation of somatodendritic 5-HT<sub>1A</sub> autoreceptors (Gartside *et al.*, 1995), decreasing 5-HT release and lowering the postsynaptic concentration of 5-HT.

Taken together, the pharmacological data obtained so far with human experimental models are compatible with the hypothesis that 5-HT enhances anxiety, evaluated by the CSCR test, whereas it inhibits fear, accessed by the SPS test.

If the predictions derived from pharmacological tests discussed above are correct, it is expected that panic patients would perform differently from healthy volunteers in the SPS but not in the CSCR test, since the former would engage the neural substrates that would be implicated in the neurobiology of PD but the latter would not. It is important to highlight that the SPS test is not considered as a model of panic attack or a probe aimed at provoking panic attacks in susceptible individuals. The rationale of the relationship between the model and the anxiety disorder is that the public speaking would engage the brain mechanisms involved in the process of innate fear, which would be impaired in PD.

As expected, our studies have shown that panic patients' response to CSCR is similar to that of controls, except for the occurrence of more spontaneous fluctuations of skin conductance along the experimental session in panic patients – a finding that is consistent with their high baseline level of subjective anxiety. In the SPS test, panic patients showed higher levels of anxiety than normal controls along the whole session, but were less responsive to the speaking challenge (Del-Ben *et al.*, 2001; Garcia-Leal *et al.*, 2005; Parente *et al.*, 2005). The profile of panic patients during the SPS test resembles the effect of the non-selective 5-HT-receptor blocker metergoline in healthy volunteers, which increased anxiety before and after the speech, but not during the speech preparation or performance (Graeff *et al.*, 1985). These

results support the suggestion that 5-HT deficiency, and therefore less inhibition of PAG, may be present in PD. Interestingly, the above SPS task did not increase cortisol secretion (Garcia-Leal *et al.*, 2005). Accordingly, neither panic attacks (reviewed in Graeff *et al.*, 2005) nor the electrical stimulation of the dorsal PAG of the rat (Schenberg *et al.*, 2008) seem to activate the hypothalamic–pituitary–adrenal axis.

Further evidence that panic patients process innate fear responses abnormally has come from a study carried out in our laboratory in patients with social anxiety disorder (SAD) submitted to the SPS test (M.C. Freitas, A. Santos Filho, F. Osório, S.R. Loureiro, C.M. Del-Ben, A.W. Zuardi, F.G. Graeff and J.A.S. Crippa, unpublished results). Although SAD and PD are different anxiety disorders they have some similarities, such as the response to the treatment with antidepressants that act on 5-HT function. Nevertheless, differently from panic patients, SAD patients have shown a greater increase in the fear induced by the SPS test, in comparison to healthy controls. Therefore, low sensitivity to the SPS test seems to be a specific feature of PD.

### ***Experimental tests of the Deakin and Graeff theory in laboratory animals: the elevated T-maze***

Since the initial findings showing that impairment of 5-HT-mediated neurotransmission causes anti-conflict effects (Robichaud and Sledge, 1969; Graeff and Schoenfeld, 1970), a large number of studies aimed at investigating the role of 5-HT in anxiety has been performed. The results, however, have been far from conclusive (Griebel, 1995; Belzung, 2001; Blanchard *et al.*, 2003; Bourin and Hascoet, 2003; Millan, 2003; Olivier *et al.*, 2003; Prut and Belzung, 2003; Sanchez, 2003). This fact is easily illustrated with results obtained in the elevated plus-maze (EPM) (Handley *et al.*, 1993; Griebel, 1995; for review, see Pinheiro *et al.*, 2007). Trying to explain these contradictory results, the British psychologist Sheila Handley proposed that the EPM engages different defense strategies, which could be influenced in opposing directions by 5-HT (Handley *et al.*, 1993). These strategies would include avoidance of the open arms (when the rat is in one of the enclosed arms) and escape from these same arms to enter a safer, enclosed arm. Based on this proposal, and trying to develop an experimental approach to test the predictions of the Deakin and Graeff (1991) theory, Graeff and co-workers developed the elevated T-maze (ETM) (Graeff *et al.*, 1993, 1998). The apparatus was built by closing the entrance of one of the enclosed arms of the elevated plus-maze. The test measures both inhibitory

avoidance (the latency to withdraw from the enclosed arm) and one-way escape (the withdrawal latency from the open arm) in the same animal. Pharmacological results have shown that diazepam impairs inhibitory avoidance but does not affect one-way escape, whereas chronic treatment with imipramine and other antidepressants increases escape latency (Graeff *et al.*, 1993; Teixeira *et al.*, 2000; Poltronieri *et al.*, 2003). The latter parameter was enhanced by the panicogenic agent cholecystokinin (Zanoveli *et al.*, 2004). These results indicate that inhibitory avoidance and escape measurements in the ETM may be modeling two different anxiety disorders, respectively GAD and PD.

In the first test of the dual role of 5-HT in the defense hypothesis, it was shown that systemic administration of d-fenfluramine, a drug that selectively releases 5-HT from the thin serotonergic fibers that come mainly from the DRN, impairs escape, whilst tending to increase inhibitory avoidance (Graeff *et al.*, 1997). These results not only fulfill the predictions from the above hypothesis, but also correlate with the results described above with the same compound administered to healthy subjects submitted

to the SPS and CSCR models. Moreover, they agree with clinical reports on antipanic effects of this drug in PD patients (Solyom, 1994; Hetem, 1996).

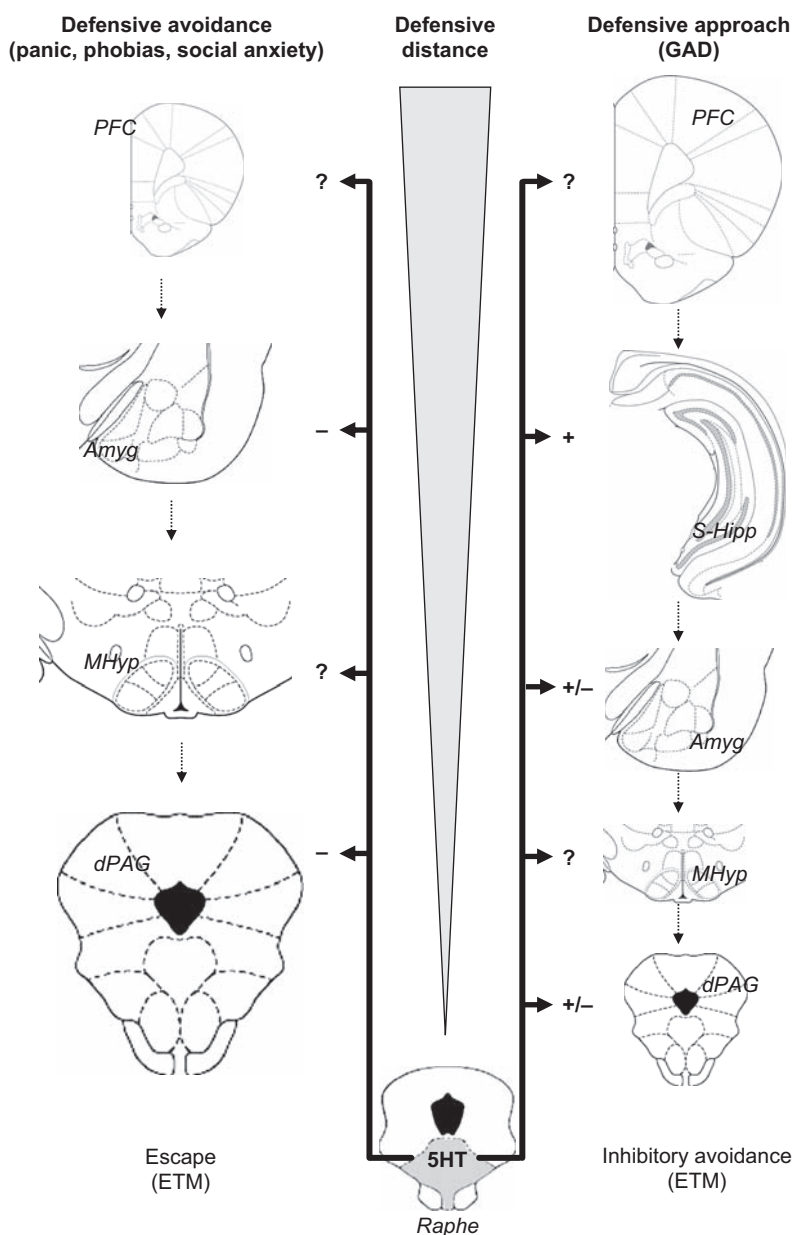

To test the dual 5-HT hypothesis more directly, a series of experiments has been conducted to explore the effects of intracerebral injection of 5-HT-acting compounds in rats submitted to the ETM (Table 1; Figure 3). Results employing microinjection of the 5-HT<sub>1A</sub> receptor antagonist WAY-100635 and the 5-HT<sub>1A</sub> agonist 8-OH-DPAT into the dorsal raphe nucleus have produced consistent results. Whereas the former drug, supposedly enhancing neuronal activity of 5-HT neurons, impaired escape and facilitated inhibitory avoidance, the latter did exactly the opposite (Sena *et al.*, 2003; Pobbe and Zangrossi, 2005).

As shown in Table 1 and Figure 3, results obtained with direct injections into projecting areas of 5-HT neurons have also produced results that are, in general, compatible with the proposal of a dual role of 5-HT (Deakin and Graeff, 1991). There are, though, some inconsistencies. Intra-dorsal PAG injection of the endogenous agonist 5-HT not only inhibited escape performance, as expected, but also caused an anxiogenic-like effect on inhibitory

**Figure 3** An alternative view of the proposal by Deakin and Graeff (1991). Instead of the rostral-caudal hierarchy originally suggested, 5-HT would play a dual role in two parallel, longitudinally organized systems (McNaughton and Corr, 2004). The approach defense system would be engaged mainly by approach-avoidance conflict. Its main neural representation would involve the septum-hippocampus and other forebrain structures. The avoidance defense system, on the other hand, would be activated when there is no tendency to approach the source of danger. In this case, the experienced emotion is fear, not anxiety. According to this proposal, fear or panic would be elicited depending on the defensive distance. Distal threat would activate forebrain structures and elicit fear, while proximal threat would activate the PAG and elicit panic. The figure also illustrates the results obtained after intracerebral injections of 5-HT agonists (see Table 1) into the dorsal periaqueductal gray (dPAG), medial hypothalamus (MHyp), septum-hippocampus (S-Hipp), amygdaloid nuclei (Amyg) or medial prefrontal cortex (PFC) on inhibitory avoidance and escape latencies of rats submitted to the elevated T-maze (ETM). +, facilitation; –, inhibition. ? indicates areas where the effects of these drugs have not yet been tested. Drawings modified from *The Rat Brain in Stereotaxic Coordinates – The New Coronal Set*, 5th edn, by George Paxinos and Charles Watson, 2005.

avoidance (Zanoveli *et al.*, 2003; de Paula Soares and Zangrossi, 2004). Other 5-HT receptor agonists, such as 8-OH-DPAT and DOI, similarly impaired escape, but with a differential effect on inhibitory avoidance – i.e., while the former compound was anxiolytic, the latter had no effect (Zanoveli *et al.*, 2003; de Paula Soares and Zangrossi, 2004). Intra-dorsal PAG administration of either 5-HT<sub>1A</sub> (WAY-100635) or 5-HT<sub>2A/2C</sub> (ketanserin, SDZ SER082) receptor antagonists, was ineffective, corroborating previous evidence indicating that in this brain region 5-HT exerts a phasic rather than tonic regulatory influence on defensive behaviors.

Similar to the results obtained in the dorsal PAG, the role of different amygdaloid 5-HT receptor subtypes in the modulation of the two tasks generated by the elevated T-maze seems to be more complex than originally thought. Thus, in the basolateral nucleus (BLA), stimulation of 5-HT<sub>1A</sub> or 5-HT<sub>2A</sub> receptors by 8-OH-DPAT and DOI, respectively, impaired rather than facilitated inhibitory avoidance acquisition, indicating an anxiolytic effect. Also unexpectedly, these compounds equally inhibited escape behavior (C. Villela de Andrade Strauss and H. Zangrossi Jr, unpublished results). However, in agreement with Deakin and Graeff's proposal, local injection of 5-HT itself or of the 5-HT<sub>2C</sub> receptor agonist MK212 caused an anxiogenic effect upon inhibitory avoidance, without changing escape performance. On the other hand, microinjection of the 5-HT<sub>2C</sub> receptor antagonist SB242084 had the opposite effect on inhibitory avoidance, also without interfering with escape (M.A. Vicente and H. Zangrossi Jr, unpublished results). Since antidepressants have been shown to down-regulate 5-HT<sub>2C</sub> after repeated administration, this finding may be related to their therapeutic effects in GAD patients.

Together, these results indicate that 5-HT, through the activation of BLA 5-HT<sub>2C</sub> receptors, plays a tonic and selective role in the mediation of inhibitory avoidance. Considering that the BLA has been proposed to assign emotional salience to both rewarding and aversive stimuli, the contradictory findings found after direct injections of 5-HT<sub>1A</sub>-, 5-HT<sub>2A</sub>- and 5-HT<sub>2C</sub>-related compounds may involve complex interference in both approach and avoidance behaviors (Lowry *et al.*, 2005).

Regarding the septo-hippocampal system, only studies assessing the involvement of 5-HT<sub>1A</sub> receptors have been published using the ETM, the results being compatible with the proposal that 5-HT is mainly implicated in the regulation of anxiety. Accordingly, 8-OH-DPAT injection into either the lateral septum or the dorsal hippocampus has an anxiogenic effect upon inhibitory avoidance, without affecting escape. In the lateral septum, the effect of 8-OH-DPAT on anxiety was opposed to that caused by the benzodiazepine midazolam. Microinjection of

WAY-100635 into either the septum or the hippocampus had no effect on the two elevated T-maze defensive tasks (dos Santos *et al.*, 2008; Viana *et al.*, 2008). However, several conflicting results suggest that the role of 5-HT in defensive responses that involve the septo-hippocampal system is more complex than originally believed. Although effects on different 5-HT receptor subtypes could help to explain these results (Gordon and Hen, 2004), most studies so far have targeted the dorsal hippocampus, an area that receives 5-HT fibers from the median rather than the dorsal raphe nucleus. The latter structure innervates mainly the ventral hippocampus, a region that has been particularly related to anxiety (Bannerman *et al.*, 2004).

As a final remark, results obtained with the administration of 5-HT-acting drugs in the ventrolateral column of the PAG point to the selective involvement of this area in anxiety modulation. In this respect, it is noteworthy that whereas electrical or chemical stimulation of the dorsal PAG evokes fight and escape responses accompanied by tachycardia and hypertension, as mentioned before, the same procedure in the ventrolateral PAG leads to behavioral inhibition (e.g., hyporeactive immobility), accompanied by bradycardia and hypotension (Carrive and Bandler, 1991). In agreement, intra-ventrolateral PAG injection of 5-HT, 8-OH-DPAT and DOI has been shown consistently to impair inhibitory avoidance acquisition, without interfering with one-way escape. Curiously, while both ketanserin and WAY-100635 were also ineffective in changing escape performance, the latter drug impaired avoidance acquisition – an effect that has been attributed to the drug interference with non-serotonergic mechanisms. Ketanserin did not affect inhibitory avoidance (de Paula Soares and Zangrossi, 2008).

Studies in the ETM have also been employed to unveil the mechanism of action of therapeutic drugs. As discussed above, several pieces of evidence suggest that the anti-panic effects of SSRIs depend on facilitation of 5-HT-mediated neurotransmission in the PAG. If this is the case, however, a general 5-HT<sub>2C</sub> receptor down-regulation induced by chronic SSRIs treatment would be expected to facilitate panic symptoms. On the other hand, the several described isoforms of 5-HT<sub>2C</sub> receptors may show distinct pharmacological characteristics and coupling mechanisms in, for example, the amygdala and the PAG (Millan, 2006a). In addition, other 5-HT receptors (5-HT<sub>2A</sub>, 5-HT<sub>1A</sub>) could play a more important role in the PAG. Recent results obtained in one of our laboratories (HZJ) support this view. Repeated treatment with imipramine, sertraline or fluoxetine enhanced the inhibitory effect of intra-dPAG injection of 5-HT<sub>1A</sub> or 5-HT<sub>2</sub> agonists on escape responses either induced by local electrical stimulation or measured in the elevated T-maze (Zanoveli

*et al.*, 2005; de Bortoli *et al.*, 2006). The same effect is also reported after long- but not short-term treatment with alprazolam, a high-potency benzodiazepine receptor agonist successfully used in the treatment of PD. Curiously, chronic treatment with alprazolam facilitates 5-HT<sub>1A</sub>- or 5-HT<sub>2A</sub>-mediated neurotransmission in the dPAG, without affecting the responsiveness of benzodiazepine receptors in the same brain area (de Bortoli *et al.*, 2008). Differently from SSRIs, buspirone failed to enhance the inhibitory effects of 5-HT<sub>1A</sub> or 5-HT<sub>2</sub> agonists on escape responses mediated by the dPAG (Zanoveli *et al.*, 2005; de Bortoli *et al.*, 2006), which could explain its lack of therapeutic efficacy in PD.

Overall, the results obtained in the ETM, particularly those in the dorsal PAG and BLA, agree with a proposed dual role of 5-HT in defensive responses. They question, however, the rostral-caudal hierarchy originally suggested by Deakin and Graeff (1991) (Figure 2). More recently, McNaughton and Corr (2004) proposed that defensive responses are organized in two parallel, longitudinally organized systems. In this view, the 'approach defense system' would deal with anxiety and be engaged mainly by approach-avoidance conflict. Its main neural representation involves the septum-hippocampus and other forebrain structures. The 'avoidance defense system', on the other hand, would be activated when there is no tendency to approach the source of danger. In this case, the experienced emotion is fear, not anxiety (Figure 3). According to this proposal, fear or panic would be elicited depending on the defensive distance. Distal threat would activate forebrain structures and elicit fear, while proximal threat would activate the PAG and elicit panic. This proposal has recently received strong support from a study in healthy volunteers using functional magnetic resonance imaging (MRI) (Mobbs *et al.*, 2007), the results of which have shown that brain activity shifts from the prefrontal cortex (PFC) to the midbrain PAG as a virtual predator capable of inflicting pain grows nearer to the virtual prey. In addition, the activity of the dorsal raphe nucleus correlated with reported subjective degree of dread and decreased confidence of escape.

### Genetic manipulations of the 5-HT system

Gene targeting manipulation developed in the last decade is a new and promising approach to investigate the biological vulnerability that underlies 'traits' of fear/anxiety (Gottesman and Gould, 2003; Holmes *et al.*, 2005; Lesch, 2005; Hariri and Holmes, 2006; Leonardo and Hen, 2006; Wrase *et al.*, 2006). Using this approach, several studies have investigated the 5-HT system. By focusing mainly on the deletion of genes coding for 5-HT receptors,

5-HT-related enzymes and the 5-HT transporter (5-HTT), these studies have produced a wealth of new evidence relating 5-HT to anxiety. They show that impairment of 5-HT<sub>1A</sub> neurotransmission results in a state of chronic fearfulness and higher responsivity to stressful stimuli. For example, 5-HT<sub>1A</sub>-knockout mice display increased anxiety-related behavior in the open field, elevated zero-maze, EPM and novelty-suppressed feeding tests (Heisler *et al.*, 1998; Parks *et al.*, 1998; Ramboz *et al.*, 1998). These effects seem to depend on postsynaptic, rather than inhibitory, autonomic receptors (Gross *et al.*, 2002). Also, mice with genetically-induced depletion of brain serotonin exhibit reduced anxiety-like behaviors and enhanced contextual fear memory. These animals also showed electrophysiological changes in hippocampal slices that can be attenuated by 5-HT or a 5-HT<sub>1A</sub> agonist (Dai *et al.*, 2008).

The anxious-like behavior displayed by 5-HT<sub>1A</sub> knockout mice in tests that involve conflict contrasts with the predictions from the Deakin-Graeff theory (see Figures 2 and 3) and with the increased inhibitory avoidance found in the ETM after direct intra-dorsal hippocampus or amygdala drug injection (Table 1). However, developmental changes induced by this genetic manipulation could be an additional factor involved in this phenotype. The presence of forebrain 5-HT<sub>1A</sub> receptors seems to be necessary, between the days 5 and 21 postnatally, for the development of mechanisms underlying normal adult defensive behavior (Gross *et al.*, 2002; Leonardo and Hen, 2005). In addition, a recent study has shown that, surprisingly, these mice perform normally in the Vogel conflict test, an animal model also based on approach-avoidance conflict that is sensitive to anxiolytic benzodiazepines. Different from the open field, elevated zero-maze or EPM, however, this test involves a discrete, non-spatial threatening stimulus (Klemenhausen *et al.*, 2006). Therefore, rather than being more 'anxious', 5-HT<sub>1A</sub> knockout mice may show a specific subtype of anxiety-related behavior, characterized by excessive behavioral inhibition to ambiguous and complex partial cues (Klemenhausen *et al.*, 2006). Recent data showing that 5-HT<sub>1A</sub> knockout mice exhibit enhanced fear conditioning to ambiguous conditioned stimuli are compatible with this proposal (Tsetsenis *et al.*, 2007). The latter study has also revealed that pharmacogenetic inhibition of the dentate gyrus blocked this effect, suggesting that the hippocampal formation plays a crucial role in the anxiety-related changes observed in these knockout animals (Klemenhausen *et al.*, 2006).

Since generalization of fear responses to ambiguous environments has been proposed to be characteristic of PD and PTSD, impairments in hippocampal 5-HT<sub>1A</sub>-receptor mediated function have been related to the pathophysiology of these disorders (Klemenhausen *et al.*, 2006).

This proposal agrees with clinical data showing hippocampal abnormalities and decreased 5-HT<sub>1A</sub>-receptor binding in these patients (van Pragg, 2004; Klemenhagen *et al.*, 2006).

Contrasting with 5-HT<sub>1A</sub> knockout mice, and corroborating the Deakin and Graeff (1991) proposal, animals with disruption of 5-HT<sub>2A</sub> show decreased anxiety in animal models (Cohen, 2005; Weisstaub *et al.*, 2006). This change disappears after selective restoration of 5-HT<sub>2A</sub> signaling in the cortex (Weisstaub *et al.*, 2006).

Compatible with the clinical reports in subjects carrying the short-allele 5-HTT gene polymorphism (see above), 5-HTT knockout mice also show increased anxiety-like behavior (Holmes *et al.*, 2003a, b) and a failure in the capacity to cope with stress (Adamec *et al.*, 2006; Hariri and Holmes, 2006). As discussed above, however, this genetic change could produce neuroadaptive compensatory effects. Similar increased anxiety-like behavior was found in wild-type mice that were treated with fluoxetine between postnatal days 4 and 21 (Ansorge *et al.*, 2004). Neuronal changes observed in these knockout animals include enhanced 5-HT synthesis and turnover, increased extracellular and decreased intracellular levels of 5-HT (Bengel *et al.*, 1998; Mathews *et al.*, 2004; Kim *et al.*, 2005), down-regulation of 5-HT<sub>1A</sub>-receptors in the dorsal raphe and at some forebrain targets (Li *et al.*, 1999, 2000; Gobbi *et al.*, 2001), down-regulation of 5-HT<sub>1B</sub> receptors (Fabre *et al.*, 2000) and up-regulation of 5-HT<sub>2A</sub>, 5-HT<sub>2C</sub> and 5-HT<sub>3</sub> receptors in forebrain regions (Rioux *et al.*, 1999; Li *et al.*, 2003; Mössner *et al.*, 2004; Hariri and Holmes, 2006).

## Conclusions

Although the precise role of 5-HT in anxiety is not yet clear, converging evidence gathered along these more than 35 years that followed the original proposal by Stein and co-workers (Wise *et al.*, 1972) has clearly shown that 5-HT (1) modulates normal defensive responses; (2) is altered in anxiety disorders; and (3) is involved in the therapeutic effects of drugs, particularly SSRIs. It has also indicated that this role is much more complex than initially thought. The modulatory effects of 5-HT on anxiety-related behavior seem to depend on several factors, including the nature of the threatening stimulus, the defensive strategies available and the brain structures engaged. In addition, these effects can suffer great interference from genetic and neurodevelopmental factors.

There is now good evidence that 5-HT inhibits a defense system engaged by proximal threats that is akin to fear/panic symptoms in humans. In this sense, facilitation

of 5-HT-mediated neurotransmission in brain structures related to this system, such as the dorsal PAG, could be part of the mechanism of the therapeutic effects of SSRIs in panic and perhaps other anxiety disorders that share some neurobiological features with panic, such as SAD and PTSD. Clinical studies have also started relating impairments in 5-HT neurotransmission with the pathophysiology of PD. In this way, a recently published study has investigated if 5-HT neurons in the DRN would be activated in rats submitted to a model of PD. The results show that rats submitted to chronic inhibition of GABA synthesis in the dorsal hypothalamus present, in contrast to controls, marked behavioral and autonomic changes when injected with sodium lactate, a well-known panicogenic agent in panic patients. The same animals fail to activate a subset of serotonergic neurons in the DRN that project to the dorsal PAG and the rostral ventromedial medulla, which is activated by lactate in control animals and is likely to inhibit both the behavioral and autonomic effects of lactate (Johnson *et al.*, 2008).

The role of 5-HT in generalized anxiety, however, is not so clear. Although several studies have been compatible with the Deakin and Graeff proposal that 5-HT facilitates anxiety while inhibiting panic, these effects may involve interference in longitudinally organized systems instead of the rostral-caudal hierarchy originally proposed. Even so, some contradictory data still persist. Despite several pieces of evidence suggesting that facilitation of 5-HT<sub>2C</sub>-mediated neurotransmission in forebrain areas facilitates anxiety, the results regarding the involvement of forebrain 5-HT<sub>1A</sub> receptors are much less clear. Studies using genetically modified animals indicate that impairment of forebrain 5-HT<sub>1A</sub>-mediated neurotransmission facilitates, rather than decreases, anxiety. This proposal has received strong support from data originating in neuroimaging studies. Although recent results suggest that this picture is not so clear (Tsetsenis *et al.*, 2007), understanding the precise role of forebrain 5-HT<sub>1A</sub> receptors in anxiety is still a challenge. In addition, we also need to understand the role of serotonin in mechanisms involved in PTSD and OCD. Although the involvement of 5-HT in neurobiological mechanism of the latter disorder is yet poorly understood, PTSD could involve 5-HT modulation of extinction processes, perhaps mediated by 5-HT<sub>1A</sub> receptors in the hippocampus or medial prefrontal cortex (van Pragg, 2004).

It is hoped that future studies combining the traditional approaches (behavioral, pharmacological, anatomical and electrophysiological) with the new molecular genetic and functional neuroimaging techniques will help us to further unveil the complex role of serotonin in normal and pathological anxiety.

# Serotonin and Aggression

Isabel M. Quadros, Aki Takahashi and Klaus A. Miczek\*

*Tufts University, Medford and Boston, Massachusetts*

**Abstract:** Traditional clinical research on the neurobiology of aggressive behavior focuses on individuals who are characterized by their impulsive, hostile, antisocial and violent traits and who show some deficiency in brain serotonin (5-HT) activity relative to those who have a propensity to engage in premeditated, calculating and instrumental aggressive acts. Preclinical research has focused on territorial, dominant or maternal aggressive behavior patterns, chiefly for reproductive purposes. Recent efforts study individuals who engage in very high levels of aggressive behavior due to genetic selection, consumption of a moderate dose of alcohol, social instigation or pharmacological insults. The early proposal that lower CSF levels of 5-HT and/or 5-HIAA were associated with a greater propensity for violent outbursts (the 'serotonin deficiency hypothesis') has been challenged by the evidence implicating receptor subtypes of the 5-HT<sub>1</sub> and 5-HT<sub>2</sub> families, the serotonin transporter (5-HTT) and metabolic enzyme monoamine oxidase A (MAOA), acting at different levels of the neuroaxis. *In vivo* techniques revealed a significant role of cortical 5-HT release during the termination of an aggressive confrontation and its consequences, rather than its initiation. Considerable clinical and preclinical evidence implicates 5-HT<sub>1A</sub>, 5-HT<sub>1B</sub> and 5-HT<sub>2A</sub> as targets for pharmacotherapeutic management of escalated aggressive behavior, which are accompanied to a varying extent by non-specific effects, whereas the genetic data for linking these receptors to specific types of aggression are less consistent. The prevalent anti-aggressive effects emerge with drugs targeting the 5-HTT, and the genetic data from human and non-human primates suggest the short allele 5-HTT polymorphism as a risk factor for violent traits, particularly in combination with environmental stress. Contrary to pharmacological inhibition of MAO, mutation of the MAOA gene in humans and mice suggests that chronically elevated 5-HT levels may promote escalated aggressive behavior, most prominently after early life maltreatment. Interactions between 5-HTT and MAOA polymorphisms suggest that complex epistatic interactions may ultimately reveal strong effects on aggressive phenotypes.

**Keywords:** violence, aggression, agonistic behavior, serotonin transporter (5-HTT, SERT), monoamine oxidase A (MAOA), antidepressants, selective serotonin reuptake inhibitors (SSRI); mutants.

## Introduction

No other transmitter substance in the brain has been linked more often to aggressive behavior than the phylogenetically old indolamine serotonin, as is well illustrated by the large number of reviews during the past four decades (see, for example, Valzelli and Garattini, 1968; Brown *et al.*, 1979a; Pucilowski and Kostowski, 1983; Miczek and Donat, 1989; Linnoila and Virkkunen, 1992; Olivier and Mos, 1992; Edwards and Kravitz, 1997; Higley and Bennett, 1999; Nelson and Chiavegatto, 2001; Miczek *et al.*, 2002, 2007). Ever since its discovery in the brain, its role in mediating physiological and behavioral

inhibition has been highlighted (Brodie and Shore, 1957). Currently, it has become evident that serotonin contributes to the neural mechanisms mediating aggressive behavior in multiple ways at different levels of the neuroaxis, and certain themes have emerged and guide the agenda for the current research efforts.

Clinical and preclinical research of the neurobiology of aggression fundamentally differ in that the former focuses most often on aggressive *traits*, and particularly maladaptive expressions of such traits, whereas the latter examines *state* changes in adaptive species-typical aggressive behavior. The most common research strategy for clinical research relates biological assays of amines or their acid metabolites or neuroimages from human subjects to their lifelong history of aggressive behavior, but these behavioral events are divorced in time from the biological

\*Corresponding author

assay. In addition to the most widely used scales for assessing aggressive and impulsive traits (see McKinley *et al.*, 1948; Buss and Durkee, 1957; Beck *et al.*, 1961; Brown *et al.*, 1979b; Barratt *et al.*, 1997; DeMoja and Spielberger, 1997), it has been possible to validate behavioral challenge methods for provoking aggressive responses under controlled laboratory conditions in parolees of violent crimes (Cherek *et al.*, 1999). Behavioral challenges, in combination with pharmacological challenges, reveal distinctive sensitivity of serotonergic receptors in violence-prone individuals (Coccaro *et al.*, 1997a, 1997b). Individuals who are characterized by their impulsive, hostile, antisocial and violent outbursts are more likely to show some deficiency in brain serotonin activity relative to those who engage in premeditated, calculating and instrumental aggressive acts (Stoff and Vitiello, 1996; Vitiello and Stoff, 1997).

One of the most important areas in clinical research during the past decade is the epigenetic analysis of the interactions between allelic variants for one of the genes that encode for serotonergic receptors, transporters or enzymes, with life experiences during critical developmental periods as determinants for adult antisocial and violent behavior. As discussed below, only after maltreatment in childhood do boys with the low monoamine oxidase A (MAOA) activity allele develop violent behavior as adults, whereas the functional polymorphism for high MAOA activity and no childhood maltreatment do not engender such adult problem behavior (Caspi *et al.*, 2002).

Animal models of aggression rely on confrontations between a territorial resident and an intruder, as is typical for mice (*M. musculus*) or between a dominant male in a colony and a challenger, as is characteristic of socially organized rats (*R. norvegicus*) or troops of monkeys (e.g., *M. mulatta*, *C. aethiops*, *S. sciureus*) (Miczek *et al.*, 2002). The resident or dominant individual engages in a well-scripted sequence of offensive acts, postures and displays, to which the intruder reacts with defensive responses and eventually submits or, if possible, flees. These patterns of agonistic interactions have evolved in a species-typical manner (as illustrated in Figure 1). Animal species that disperse during their reproductively active phase of life, and those that live cohesively, engage in aggressive behavior in order to secure the resources for reproduction or to protect the offspring. Recent efforts aim to model pathologically violent behavior in humans by a focus on genetic and environmental conditions that engender escalated aggressive behavior in mice and rats relative to the species-normative patterns (Table 1). These efforts focus on subsets of individuals that engage in very high levels of aggressive behavior due to genetic selection, consumption of a moderate dose of alcohol, social instigation, or pharmacological insults (Miczek *et al.*, 1998a, 2002, 2007; Miczek and Fish, 2005; Haller and Kruk, 2006; Natarajan *et al.*, 2009).

**Figure 1** Mouse agonistic behavior. Behaviors of resident and intruder mice engaged in an aggressive confrontation: (A) the resident leaps and bites the intruder as the intruder attempts to escape; (B) the resident (*right*) threatens as the intruder (*left*) holds a defensive upright posture; (C) the resident investigates the intruder's anogenital region; (D) the resident pursues the fleeing intruder; (E) both resident and intruder engage in a mutual upright defensive posture. <b>Territorial aggression (resident–intruder test),</b> mainly in mice and hamsters	In the established territory. In the laboratory, home-cage of experimental male ( <i>resident</i> ) where it is pair-housed with a female. A male stimulus animal ( <i>intruder</i> ) that is group housed with other males is introduced into resident's cage.	Frequency of attack bite, sideways threat, tail-rattle, pursue, upright posture. Latency to the first bite.	Van Oortmerssen and Bakker, 1981 Eibl-Eibesfeldt, 1950 Miczek and O'Donnell, 1978 Crawley <i>et al.</i> , 1975
<b>Maternal aggression,</b> mainly in rats, mice, and hamsters	Home-cage of lactating females from postpartum days 1 to 7. Either male or female intruder is introduced into dam's cage.	Frequency of attack bite (especially directed at the snout and the face), sideways threat, tail-rattle, pursue, upright posture. Latency to the first bite	Hurst, 1987 Sgoifo <i>et al.</i> , 1992 Lonstein and De Vries, 2000 Noirot <i>et al.</i> , 1975 Haney <i>et al.</i> , 1989
<b>Female aggression,</b> mainly in primates and rodents.	Dominant hierarchy among female monkeys. In the laboratory settings, female rodent pair-housed with a breeding male. Sexually matured female is introduced as an intruder.	Harrassing attacks by dominant female. Frequency of attack bite, sideways threat, tail-rattle, pursue, upright posture. Latency to the first bite	Smuts, 1986 Palanza <i>et al.</i> , 2005 DeBold and Miczek, 1981 Zitzman <i>et al.</i> , 2004
<b>Isolation-induced aggression</b> (similar to territorial aggression)	Male isolated for some time, ranging from 24 hours to 8 weeks prior to <i>resident–intruder</i> encounter.	Frequency of attack bite, sideways threat, tail-rattle, pursue, upright posture. Latency to the first bite.	Malick, 1979 Valzelli and Bernasconi, 1979 Cairns and Nakelski, 1971 Yen <i>et al.</i> , 1959
<b>(B) Escalated aggressive behavior</b>			
<b>Alcohol-heightened aggression,</b> mainly in rats and mice	Animals receive ethanol (1.0 g/kg) intraperitoneally or orally before the <i>resident–intruder</i> encounter.	(These three methods measure aggressive behavior using the <i>resident–intruder</i> procedure) Frequency of attack bite, sideways threat, tail-rattle, pursue, upright posture. Latency to the first bite.	Peeke and Figler 1981 Cherek <i>et al.</i> , 1984 Blanchard <i>et al.</i> , 1987 Miczek <i>et al.</i> , 1992, 1998 Miczek and de Almeida, 2001
<b>Social provocations (instigations),</b> mainly in hamsters, mice, and rats	A resident male pre-exposed to another breeding male in his home-cage without direct agonistic interaction (stimulus animals are behind protective screen), followed by <i>resident–intruder</i> encounter.		Heiligenberg, 1974 Potegal and Tenbrink, 1984 Potegal, 1991 Fish <i>et al.</i> , 1999
<b>Frustration-heightened aggression</b>	A resident male trained to obtain rewards. Before the <i>resident–intruder</i> encounter, the reward is omitted.		Berkowitz, 1993 De Almeida and Miczek, 2002 Cherek <i>et al.</i> , 1997
<b>Affective defense ('rage'),</b> mainly in cats	Electrical stimulation (0.2–0.8 mA, 63 Hz, 1 ms per half cycle duration) delivered in medial hypothalamus or midbrain periaqueductal gray.	Hissing, arching of the back, retraction of the ears, piloerection, unsheathing of the claws, papillary dilatation and paw striking	Leyhausen, 1979 Siegel <i>et al.</i> , 1999 Hess, 1954

### The emergence of the serotonin–aggression link

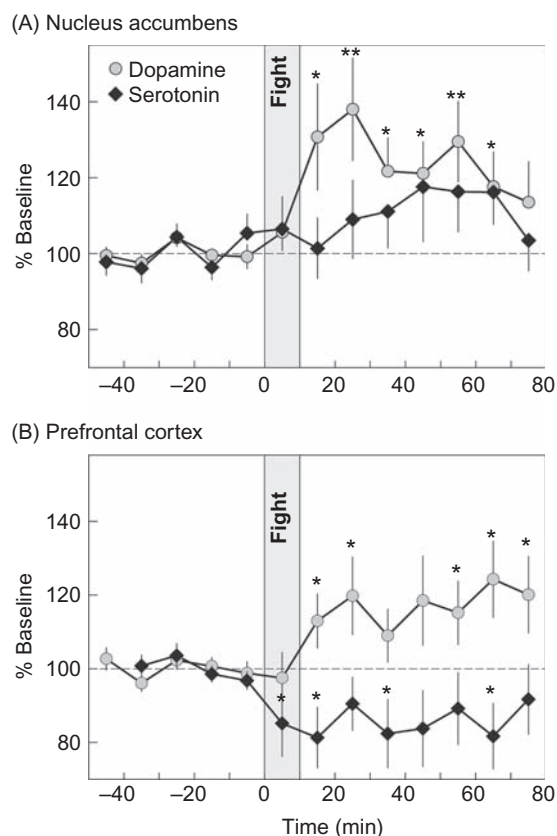

Given the prominent role of serotonin in the neurobiology of aggression, it is not surprising that 5-HT signaling mechanisms are promising pharmacotherapeutic targets in the management of impulsive, aggressive and violent behavior, as discussed in the next section. The initial evidence suggesting that 5-HT might have an inhibitory action on aggressive behavior stemmed from a study in isolated mice. *Post-mortem* assays of the brains of isolated aggressive mice revealed lower brain 5-HT and 5-HIAA contents and turnover when compared with group-housed control mice (Giacalone *et al.*, 1968). In humans, concordant evidence of the involvement of 5-HT function in violent behavior originated from US marines with a life history of repeated aggressive behavior. In this population of marines, the levels of the 5-HT metabolite 5-HIAA detected in the cerebrospinal fluid (CSF) were inversely correlated with the life history of aggression (Brown *et al.*, 1979a, 1979b). The evidence on suppressed CSF 5-HIAA as a biomarker for increased aggressive behavior is, however, divided. On the one hand, the proposal that lower CSF levels of 5-HT and/or 5-HIAA were associated with a greater propensity for violent outbursts (the ‘serotonin deficiency hypothesis’) was further supported by studies in patients with antisocial personality disorder and others showing impulsive aggression and type-II alcoholism (Linnoila *et al.*, 1983; Kruesi *et al.*, 1990; Virkkunen and Linnoila, 1993a; Pihl and LeMarquand, 1998; Lesch and Merschdorf, 2000; Placidi *et al.*, 2001). Likewise, negative correlations between CSF 5-HIAA levels and a history of impulsive aggression were observed in non-human primates (Higley *et al.*, 1992, 1996b; Westergaard *et al.*, 1999; Manuck *et al.*, 2003; Fairbanks *et al.*, 2004). On the other hand, many studies in humans, non-human primates and rodents failed to find such inverse correlations between 5-HT or 5-HIAA and levels of aggressive behavior (see, for example, Yodyingyuad *et al.*, 1985; Miczek and Donat, 1989; Gardner *et al.*, 1990; Lidberg *et al.*, 2000; van der Vegt *et al.*, 2003a). This observation raises the possibility that the importance of serotonergic deficiency for trait aggression could be restricted to groups of individuals who engage in aggressive behavior in an impulsive, escalated manner, rather than in individuals with other types of aggressive behavior (Coccaro, 1989; Virkkunen and Linnoila, 1993b; Mehlman *et al.*, 1994). For example, in male rats showing species-typical aggression, 5-HT and 5-HIAA levels in the CSF were actually positively correlated with trait aggression, indexed as percentage of time spent in aggressive behavior towards a conspecific male in a resident–intruder confrontation (van der Vegt *et al.*, 2003a). In that study, when 5-HT terminals were lesioned with the neurotoxin

5,7-dihydroxytryptamine (5,7-DHT), producing a reduction in CSF 5-HT levels, aggressive behavior was not affected (van der Vegt *et al.*, 2003a). Thus, it seems likely that when aggression occurs in a more species-typical social context, with an ethological function and purpose (i.e., establishment of territory and dominance), the association with 5-HT function is different (if not opposite) from what is observed in pathological, escalated types of aggression.

Similar patterns are observed using the pharmacological challenge approach to assess 5-HT function in individuals with a history of aggressive outbursts, administering a 5-HT agonist and assaying an endocrine response in the blood. In these studies, patients with personality and mood disorders (Coccaro *et al.*, 1989, 1997b), violent alcoholics (Moss *et al.*, 1990; Handelsman *et al.*, 1996) and violent offenders (O’Keane *et al.*, 1992) showed a blunted plasma prolactin response after receiving administration of 5-HT agonists (such as fenfluramine or buspirone). These results supported the proposal of an inverse correlation between 5-HT function and a history of impulsive aggressive behavior, and implicated 5-HT projections to the hypothalamus as an important pathway associated with aggression (Coccaro, 1992). However, similarly to studies of CSF 5-HT levels, some studies using the pharmacological challenge approach also failed to reveal an association between prolactin responses and the propensity to engage in aggressive acts (Halperin *et al.*, 1994; Pine *et al.*, 1997; Handelsman *et al.*, 1998).

Due to the prolonged period that separates the time when 5-HT, 5-HIAA or prolactin levels are assayed from the actual aggressive events, the results supporting a serotonin deficiency hypothesis reflect a *trait* for impulsive aggression in individuals with lower basal 5-HT/5-HIAA levels, but offer little explanation regarding the role for 5-HT in the preparation, execution and recovery from the actual aggressive acts and behaviors (Coccaro, 1989; Miczek *et al.*, 1994). Furthermore, analysis of transmitter and metabolites in the CSF lacks neuroanatomical resolution. It is not possible to determine which 5-HT brain pathways contribute primarily to the 5-HT/5-HIAA contents that are measured in the CSF, which can generate a confounding factor in the interpretation of these data.

Using *in vivo* microdialysis techniques, transient changes in 5-HT extracellular levels were monitored before, during, after, and in anticipation of an aggressive encounter in rats. In one study, reduced 5-HT levels in the prefrontal cortex were revealed during the aggressive confrontation, while no changes in 5-HT were detected in another terminal region, the nucleus accumbens (Van Erp and Miczek, 2000). Interestingly, reduced 5-HT in the prefrontal cortex was detected for at least 1 hour after the termination of the fight, and after the fight dopamine levels were increased in the nucleus accumbens (Figure 2; Van Erp and Miczek, 2000). On the other hand, in rats that

**Figure 2** Dopamine and serotonin during aggression. Measurements of extracellular dopamine and serotonin via *in vivo* microdialysis in resident male rats before, during and after a confrontation with an intruder. (A) In the nucleus accumbens (*top panel*), dopamine levels (gray circles) rise and remain elevated after the confrontation, while serotonin levels (black diamonds) do not significantly change. (B) In the prefrontal cortex (*bottom panel*), dopamine levels rise after the confrontation, while serotonin levels decline and remain lower after the confrontation. Samples were collected every 10 minutes and levels are expressed as mean (SEM, vertical lines) percent of baseline. Baseline was measured for 50 minutes before the fight. The vertical light-gray bar indicates the occurrence of the 10-minute fight. \* and \*\* represent significance from baseline (dashed line) at the  $P < 0.05$  and  $P < 0.01$  levels, respectively. were expecting an aggressive confrontation (which had previously occurred every day at the same time), 5-HT levels were reduced in the nucleus accumbens even in the absence of the actual confrontation (Ferrari *et al.*, 2003). Thus, mesocorticolimbic 5-HT activity is transiently modified during the aggressive confrontation, and in the phases that precede and follow the aggressive encounter (Van Erp and Miczek, 2000; Ferrari *et al.*, 2003).

Adding another degree of complexity to the serotonin–aggression link is the consideration that the effects of 5-HT are mediated by a wide variety of receptors, and 5-HT action is modulated by other synaptic and non-synaptic

components (e.g., the 5-HT transporter or the synthetic enzyme, tryptophan hydroxylase). Monitoring the extracellular 5-HT content in one particular brain region reveals the summation of 5-HT release, uptake and presynaptic gating processes in that region. Pharmacological manipulations of pre- and postsynaptic components of the 5-HT system, particularly the 5-HT<sub>1</sub> and 5-HT<sub>2</sub> receptor families as well as 5-HT transporter, markedly affect aggressive behavior, and will be discussed below. Furthermore, there are prominent genetic influences on aggressive behavior and temperament. Heritability of antisocial behavior has been estimated to range from 28 percent to 47 percent (Coccaro *et al.*, 1997c). In animal models, selective breeding has been successful for aggressive behavior in mice and rats (Lagerspetz *et al.*, 1968; Cairns and Nakelski, 1971; van Oortmerssen and Bakker, 1981), which also suggests that genetics can affect aggression as a trait. It is of interest to discuss the genes that modulate aggression by their direct or indirect regulation of 5-HT pathways. Gene targeting techniques are useful to elucidate the effects of one particular gene on behavior, and analysis of gene polymorphisms can uncover a genetic basis for individual differences in aggressive behavior. Here, we will further discuss the serotonin–aggression link, focusing on recent developments and tools for pharmacological and genetic assessment of 5-HT function.

## Modulation of 5-HT synthesis and aggression

### Tryptophan depletion or supplementation and aggression

Removing the aromatic acid precursor L-tryptophan from the diet causes depletion of plasma tryptophan and brain serotonin (Delgado *et al.*, 1990; Nishizawa *et al.*, 1997). Acute tryptophan depletion in healthy male volunteers promotes increased aggressive responding in experimental models of human aggression (Pihl *et al.*, 1995; Moeller *et al.*, 1996; Bjork *et al.*, 1999), suggesting that acutely decreased levels of 5-HT could be associated with increased display of aggressive behavior. In one of these studies, men received a low-tryptophan diet for 24 hours, followed by a tryptophan-free amino acid mixture drink on the test day, and aggressive responding was assessed using the Point Subtraction Aggression Paradigm. Aggression responding was increased 5–6 hours after drinking the tryptophan-free mixture, and at the same time corresponding low levels of plasma tryptophan were detected (Moeller *et al.*, 1996). Conversely, supplementation of tryptophan in the diet has been shown to increase 5-HT synthesis in the brain, resulting in decreased irritability and aggression in experimental human settings

(see Young and Leyton, 2002, for a review). According to these results, a proximal and direct role for 5-HT is proposed whereby acute reductions in 5-HT would promote increased risk to engage in violent behavior, whereas chronic maintenance of higher 5-HT concentrations would have protective anti-aggressive effects.

In rodents, depletion of tryptophan from the diet reduces 5-HT synthesis in the brain (Gessa *et al.*, 1974), and further supports the negative correlation between 5-HT levels and aggressive behavior. While a tryptophan-free diet resulted in augmented isolation-induced aggression in mice and shock-induced defensive reactions in rats, tryptophan supplementation reduced some types of aggressive behavior (Kantak *et al.*, 1980a, 1980b; Lasley and Thurmond, 1985). In humans and lower animals, however, it remains unclear whether or not manipulation of tryptophan availability, which presumably regulates 5-HT synthesis, will also result in augmented or decreased brain 5-HT release and function (Young and Leyton, 2002). Overall, results with tryptophan (or 5-HTP) depletion or supplementation should be interpreted in light of some limitations. These manipulations produce effects that are not specifically related to 5-HT, including alteration of other amines (e.g., melatonin and tryptamine), alterations in protein synthesis, and changes in mood and temperament (Young and Leyton, 2002).

### ***Tryptophan hydroxylase and aggression***

Tryptophan hydroxylase is the rate-limiting enzyme in the synthesis of serotonin, catalyzing the formation of 5-hydroxytryptophan (5-HTP) from the dietary precursor L-tryptophan.

#### ***Pharmacology of tryptophan hydroxylase and aggression***

In preclinical studies, para-chlorophenylalanine (pCPA), an irreversible inhibitor of tryptophan hydroxylase, is used as a pharmacological tool to deplete 5-HT (Koe and Weissman, 1966; Jequier *et al.*, 1967). Significant depletion of 5-HT levels is found for approximately 2 weeks after pCPA administration, with peak depletion (approximately 80–90 percent depletion) 2–3 days after pCPA treatment (Aghajanian *et al.*, 1973; Vergnes *et al.*, 1986). Behaviorally, pCPA treatment increased defensive reactions to pulses of electric shock to the feet of a pair of rats, and these effects could be attributed to altered pain sensitivity after serotonin depletion (Ellison and Bresler, 1974; Knutson *et al.*, 1979). Inhibition of tryptophan hydroxylase also escalated offensive, but not defensive, aggression in a resident–intruder encounter in rats (see, for example, Vergnes *et al.*, 1986; Keele, 2001). These

results suggest that depletion of 5-HT would facilitate and/or promote escalated levels of aggressive behavior in rodents. Interpretation of these findings is complicated due to the pervasive effects of depletion of whole brain 5-HT that extend from changes in perception, sensory functions and motor routines that are necessary for the display of different types of aggression.

#### ***Genetics of tryptophan hydroxylase and aggression***

Variations in tryptophan hydroxylase (TPH) activity can directly affect 5-HT neurotransmission. Several studies have shown that polymorphisms in the TPH1 or TPH2 gene change the enzyme activity and 5-HT level (Jonsson *et al.*, 1997 for the TPH1 gene; Zhang *et al.*, 2004, 2005; Lin *et al.*, 2007; and Cichon *et al.*, 2008 for the TPH2 gene). Two single nucleotide polymorphisms (SNPs) in tight linkage disequilibrium, A218C and A779C located in the intron of TPH1 gene (which are often referred to as the U (upper) and L (lower) alleles), have been shown to be associated with state and trait anger as assessed by interview and self report questionnaires (Manuck *et al.*, 1999; Rujescu *et al.*, 2002). Lower CSF 5-HIAA levels have been observed in healthy men, but not women, with the U allele (Jonsson *et al.*, 1997), whereas the lowest CSF 5-HIAA was observed in LL carriers diagnosed with antisocial alcoholism (Nielsen *et al.*, 1994). Apparently, both U and L alleles may relate to different types of aggression. Hennig *et al.* (2005) performed factor analysis on the Buss-Durkee Hostility Inventory (BDHI) and found two factors, named as ‘neurotic hostility’ and ‘aggressive hostility’. Neurotic hostility is characterized by irritability, resentment, verbal hostility and guilt, whereas aggressive hostility represents a more ‘cold’ aggression, including assault and negativism but low guilt. Individuals with the UU allele showed higher aggressive hostility but slightly lower neurotic hostility (Hennig *et al.*, 2005), whereas LL homozygote showed a higher level of impulsivity in the measurements that focused more on neurotic hostility (New *et al.*, 1998). This may explain controversial results about the association between the polymorphisms and aggression; depending on which dimensions of aggressive behavior are measured, the association pattern may change.

In mouse models, the focus has been on the Tph2 gene, because Tph2 is preferentially expressed in the brain whereas Tph1 is more widely distributed throughout the body (Walther *et al.*, 2003). Mice with an R439H point mutation in the Tph2 gene have strongly reduced 5-HTP, 5-HT and its acidic metabolite levels in brain (Beaulieu *et al.*, 2008). This mutant mouse showed increased aggressive behaviors in the social interaction test in a neutral arena where, typically, very low levels of aggression are seen (Beaulieu *et al.*, 2008). In contrast, another polymorphism

in Tph2, C1473G, which inhibits Tph2 activity in the mid-brain, reduced the intensity of aggression in mice (Osipova *et al.*, 2009). The mouse data on the R439H mutation in the Tph2 gene may be relevant to a large association study in children with attention-deficit hyperactivity disorder (ADHD), which identified a TPH2 gene polymorphism associated with impulsivity (Oades *et al.*, 2008).

### **Summary for 5-HT synthesis and aggression**

Evidence from pharmacological manipulations suggests that reduction of 5-HT synthesis (tryptophan depletion and pCPA treatment) increases aggressive behaviors. However, those effects depend on the type of aggressive behavior examined. Genetic studies indicate that both alleles, L and U, of polymorphism in the TPH1 gene are involved in human aggression, but each allele is associated with a different type of aggression. There is support to suggest that reduced central 5-HT activity is implicated in abnormal 'irritable' impulsive aggression but not in species-typical aggressive behaviors (Mehlman *et al.*, 1994; Coccaro *et al.*, 1989; de Boer and Koolhaas, 2005).

### **5-HT receptors and aggression**

Considerable evidence implicates 5-HT receptors in the neural mechanisms for aggressive behaviors in various animal species. In particular, receptors of the 5-HT<sub>1</sub> and 5-HT<sub>2</sub> families are of significance in the control of aggressive behavior, based on initial pharmacological studies (Miczek *et al.*, 2002; Olivier, 2004). Other receptor subtypes (e.g., 5-HT<sub>5,6,7,1e,1f</sub>) have not been explored as of yet, primarily because of a lack of adequate pharmacological tools. There is some suggestion of the involvement of 5-HT<sub>3</sub> receptors in aggression (Rudissaar *et al.*, 1999; Ricci *et al.*, 2004; McKenzie-Quirk *et al.*, 2005); however, further investigation will be needed. Here we will discuss chiefly the data implicating 5-HT<sub>1</sub> and 5-HT<sub>2</sub> receptors in aggressive behaviors, since abundant data are available for these receptors.

#### **5-HT<sub>1</sub> receptors and aggression**

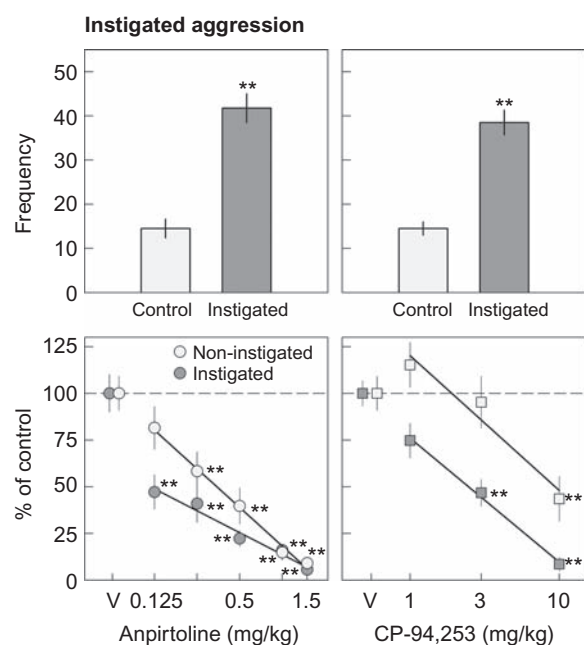

##### *Pharmacology of 5-HT<sub>1</sub> receptors and aggression*

Clinically, the 5-HT<sub>1A</sub> receptor partial agonist buspirone reduces aggressive behavior in mentally retarded patients (Ratey *et al.*, 1991; Kavoussi *et al.*, 1997). Preclinically, systemic injections of 5-HT<sub>1A</sub> receptor agonists reduce aggressive behavior across several species, including fish, amphibian, birds, rodents, guinea pigs and non-human

primates (Tompkins *et al.*, 1980; Dompert *et al.*, 1985; Lindgren and Kantak, 1987; Blanchard *et al.*, 1988; McMillen *et al.*, 1988; Haug *et al.*, 1990; Nikulina *et al.*, 1992; Olivier and Mos, 1992; Sanchez *et al.*, 1993; Bell and Hobson, 1994; Muehlenkamp *et al.*, 1995; Joppa *et al.*, 1997; Miczek *et al.*, 1998b; de Boer *et al.*, 1999, 2000; Sperry *et al.*, 2003; de Boer and Koolhaas, 2005; Clotfelter *et al.*, 2007; Ten Eyck, 2008a). Only one exception was observed, in fruit flies (*Drosophila melanogaster*), where 8-OH-DPAT treatment increased aggressive behavior (Johnson *et al.*, 2009). Although 5-HT<sub>1A</sub> agonists have consistent anti-aggressive effect in vertebrates, most of those compounds have an unfavorable profile of side-effects, including sedation, slow motor routines, reduced social interest or stereotypic behavior in the dose range that produces effective reduction of aggressive behaviors (Olivier *et al.*, 1995; Joppa *et al.*, 1997; Miczek *et al.*, 1998b; de Boer *et al.*, 2005). Some 5-HT<sub>1A</sub> agonists, at least in specific rat strains, can reduce aggressive behavior specifically, without changing the other non-aggressive behaviors (i.e., alnespirone and S-15535; de Boer *et al.*, 1999, 2000; de Boer and Koolhaas, 2005). It is possible that those compounds act on a subpopulation of 5-HT<sub>1A</sub> receptors to exert this anti-aggressive effect, and thereby achieve higher behavioral specificity. Antagonists with preferential action at 5-HT<sub>1A</sub> receptors, such as WAY-100635, blocked the anti-aggressive effect of 5-HT<sub>1A</sub> agonists, while having no effect by themselves on aggression (Miczek *et al.*, 1998; Mendoza *et al.*, 1999; de Boer and Koolhaas, 2005).

5-HT<sub>1B</sub> receptor agonists seem more specific in their anti-aggressive effects than 5-HT<sub>1A</sub> agonists. Systemic injection of 5-HT<sub>1B</sub> agonists reduced aggressive behavior without sedation or motor or sensory impairment in mice and rats (Olivier *et al.*, 1990; Fish *et al.*, 1999; de Almeida *et al.*, 2001; de Almeida and Miczek, 2002; Miczek *et al.*, 2002, 2004; Olivier, 2004; de Boer *et al.*, 2005). Figure 3 shows that 5-HT<sub>1B</sub> agonists effectively decreased escalated level of aggressive behavior (Fish *et al.*, 1999; de Almeida and Miczek, 2002). These effects were antagonized by the 5-HT<sub>1B/1D</sub> antagonist GR-127935, which confirmed that the anti-aggressive effects of these compounds were mediated by 5-HT<sub>1B</sub> receptors (de Boer and Koolhaas, 2005). However, it is known that there is an amino acid difference in the binding domain of 5-HT<sub>1B</sub> receptors between humans and rodents, and therefore pharmacological sensitivity and specificity of 5-HT<sub>1B</sub> agonists in rodents may differ from those in humans (Olivier, 2004).

It remains to be resolved exactly how and where 5-HT<sub>1A</sub> and 5-HT<sub>1B</sub> receptor agonists modulate 5-HT neurotransmission and reduce aggressive behaviors. One site of action for 5-HT<sub>1</sub> receptors is the autoreceptors,

**Figure 3** (Top panels) Effects of social instigation on aggressive behavior by a resident mouse toward a male intruder. Bars represent the mean frequency  $\pm$  SEM (vertical lines) of attack bites under control (light-gray) and instigated (dark-gray) conditions. Asterisks denote statistical significance from control (\*\* $P < 0.01$ ). (Bottom panels) Preferential reduction of instigated aggressive behavior by the 5-HT<sub>1B</sub> agonist anpirtoline (left panel, filled circles) and CP-94,253 (right panel, filled squares). Symbols represent the mean frequency of attack bites, expressed as a percentage of vehicle (V) baseline,  $\pm$  SEM. Light-gray symbols represent non-instigated fighting and dark-gray symbols represent instigated levels of fighting. Asterisks denote significance from vehicle baseline ( $P < 0.05$ ). which can be localized at either the somata or the synaptic terminals of 5-HT neurons. Stimulation of 5-HT<sub>1</sub> autoreceptors can inhibit 5-HT neuronal activity and 5-HT impulse flow. On the other hand, agonists that act postsynaptically on projection sites of 5-HT<sub>1</sub> receptors (heteroreceptors) may actually be based on increased 5-HT neurotransmission. To identify neural sites of action of the anti-aggressive effect by 5-HT<sub>1A</sub> and 5-HT<sub>1B</sub> receptor agonists, intracerebral microinjection techniques have been used.

5-HT in the forebrain derives mainly from ascending projections that originate in the dorsal and median raphe nuclei (DRN and MRN, respectively) in rodents. Microinfusion of 5-HT<sub>1A</sub> agonists into the DRN consistently reduced aggressive behavior in rats and mice (Mos *et al.*, 1993; van der Vegt *et al.*, 2003b; Faccidomo *et al.*, 2008). 5-HT<sub>1A</sub> agonist injection into the MRN also reduced aggressive behavior of female rats (de Almeida and Lucion, 1997). Moreover, intra-DRN microinjection

of 5-HT<sub>1B</sub> agonists reduced aggressive behavior in mice (Bannai *et al.*, 2007; Faccidomo *et al.*, 2008). However, intra-raphé injection of either 5-HT<sub>1A</sub> or 5-HT<sub>1B</sub> agonists concomitantly reduced activity and social interest (Mos *et al.*, 1993; Bannai *et al.*, 2007; Faccidomo *et al.*, 2008). Microinjection of 5-HT<sub>1A</sub> and 5-HT<sub>1B</sub> receptor agonists reduced 5-HT neuronal activity and 5-HT release in the projection sites (Sprouse and Aghajanian, 1987; Bonvento *et al.*, 1992; Adell *et al.*, 2001); therefore, these results suggest that reduction of 5-HT neurotransmission reduces aggressive behaviors, which challenges the 5-HT deficiency hypothesis (de Boer and Koolhaas, 2005).

On the other hand, the importance of 5-HT<sub>1A</sub> and 5-HT<sub>1B</sub> receptors on projection sites has been emphasized in studies using lesion or depletion of raphe 5-HT neurons either by systemic administration of the tryptophan hydroxylase inhibitor pCPA or by intracerebral injection of the 5-HT neurotoxin, 5,7-dihydroxytryptamine (5,7-DHT). The logic is that by depleting 5-HT neurons, one can observe the effect of 5-HT<sub>1</sub> agonists on postsynaptic receptors. If only somata and presynaptic autoreceptors are the site of action of 5-HT<sub>1A</sub> and 5-HT<sub>1B</sub> agonists, pCPA or 5,7-DHT treatment should eliminate the anti-aggressive effect of 5-HT<sub>1A</sub> and 5-HT<sub>1B</sub> agonists. However, lesions or depletion of 5-HT neurons did not affect anti-aggressive effects of 5-HT<sub>1A</sub> and 5-HT<sub>1B</sub> agonists (Sijbesma *et al.*, 1991; Sanchez and Hyttel, 1994; Miczek *et al.*, 1998b; de Almeida *et al.*, 2001), suggesting postsynaptic 5-HT receptors as critical sites of action. This interpretation needs to be qualified, since these neurotoxic lesions are typically incomplete and spare a considerable percentage of presynaptic receptors (de Boer and Koolhaas, 2005). In the projection sites of 5-HT neurons, it is often hypothesized that 5-HT<sub>1B</sub> receptors modulate 5-HT release from synaptic terminal as autoreceptors, whereas both 5-HT<sub>1A</sub> and 5-HT<sub>1B</sub> receptors change activation of postsynaptic neurons (Olivier and Mos, 1992). Figure 4 shows a summary of the effects of regional 5-HT<sub>1A</sub> and 5-HT<sub>1B</sub> receptor populations on different kinds of aggressive behaviors. A reduction of territorial aggression was observed when 5-HT<sub>1A</sub> and 5-HT<sub>1B</sub> agonists are microinjected into the medial pre-optic area, lateral septum or orbitofrontal cortex in mice (Cologer-Clifford *et al.*, 1997; de Almeida *et al.*, 2006). Vasopressin-escalated aggression in hamsters was reduced by microinjection of a 5-HT<sub>1A</sub>, but not 5-HT<sub>1B</sub>, agonist into the anterior hypothalamus (Ferris *et al.*, 1999). Interestingly, a 5-HT<sub>1B</sub> receptor agonist increased alcohol-heightened aggressive behavior when it was microinjected into the medial prefrontal cortex (Faccidomo *et al.*, 2008). This escalation may be due to reduction of 5-HT neurotransmission by acting on presynaptic terminals of 5-HT neurons. However, a 5-HT<sub>1A</sub> agonist increased maternal aggression when it

**Figure 4** Modulation of aggressive behaviors by microinjections of 5-HT<sub>1A</sub>, 5-HT<sub>1B</sub>, and 5-HT<sub>2A/2C</sub> receptor agonists. Text boxes show that local injection of 5-HT<sub>1A</sub> receptor (1A), 5-HT<sub>1B</sub> receptor (1B), or 5-HT<sub>2A/2C</sub> receptor (2A/2C) agonist increases (↑), decreases (↓) or has no effect ('0') on territorial, escalated, maternal, and defensive aggressive behaviors. Serotonergic neurons originated from raphe nuclei project to several brain areas. To see the full color version of this figure please refer to the colour plate in the back of the book. Copies produced via our print on demand service do not contain color plate. If your copy does not have the color plate, please go to this website to view the figure in color [www.elsevierdirect.com/companions/9780123746344](http://www.elsevierdirect.com/companions/9780123746344)

was microinjected into the medial septal area (de Almeida and Lucion, 1997), and this result is inconsistent with the 5-HT deficiency hypothesis. Regarding defensive aggression, 5-HT<sub>1A</sub> agonist in the periaqueductal gray (PAG) and medial hypothalamus reduced defensive hissing in cats (Shaikh *et al.*, 1997; Hassanain *et al.*, 2003). Most of the evidence suggests that 5-HT<sub>1A</sub> and 5-HT<sub>1B</sub> agonists reduce territorial aggression by acting at somatodendritic presynaptic and postsynaptic receptor sites. In contrast, in maternal and escalated types of aggression, increased aggressive behavior was observed after a 5-HT<sub>1A</sub> agonist was injected into medial septal area and after a 5-HT<sub>1B</sub> agonist was injected into medial prefrontal cortex. Further studies are required to delineate the mechanisms for those pro-aggressive effects.

#### Genetics of 5-HT<sub>1</sub> receptors and aggression

In contrast to the strong implication of 5-HT<sub>1A</sub> receptor in aggressive behavior from pharmacological research, no prominent linkage has been reported with the polymorphisms in the gene for 5-HT<sub>1A</sub> and aggression so far. However, there is evidence for a correlation between 5-HT<sub>1A</sub> receptor expression and aggression. Human PET studies found a higher 5-HT<sub>1A</sub> receptor distribution in the prefrontal cortex of subjects with higher aggression scores in self-report questionnaires (Witte *et al.*, 2008). Also, rats selected by higher defensive reactions showed reduced 5-HT<sub>1A</sub> receptor expression in several brain areas (Popova *et al.*, 1998). It is possible that the polymorphisms which

directly or indirectly affect 5-HT<sub>1A</sub> receptor transcription may be associated with aggressive or defensive responses. 5-HT<sub>1A</sub> receptor knockout mice engaged in less aggressive behavior relative to wild-type controls, which also implicates possible involvement of 5-HT<sub>1A</sub> gene in aggressive behavior (Zhuang *et al.*, 1999). Given the consistent pharmacological data on anti-aggressive effects of 5-HT<sub>1A</sub> agonists, lack of complementary genetic data is surprising.

On the other hand, data from several genetics studies have shown the involvement of 5-HT<sub>1B</sub> receptor in aggressive behavior. Male mice with disrupted 5-HT<sub>1B</sub> receptor expression (*Htr1b*<sup>-/-</sup>) increased aggressive behavior in the resident-intruder test after a month of isolation (Saudou *et al.*, 1994; Bouwknecht *et al.*, 2001). However, due to very low (close to zero) levels of aggressive behavior in the wild-type mice (129/Sv-ter), the number of attacks in *Htr1b*<sup>-/-</sup> was low compared to other strains of mice. These mice displayed behavioral disinhibition in other behavioral tests, including hyperlocomotor activity (Ramboz *et al.*, 1995; Brunner *et al.*, 1999), drug intake (Crabbe *et al.*, 1996; Rocha *et al.*, 1998), anxiety (Brunner *et al.*, 1999; Malleret *et al.*, 1999) and autonomic hyper-reactivity to novelty (Bouwknicht *et al.*, 2001). Female *Htr1b*<sup>-/-</sup> mice also showed increased aggressive behavior during the postpartum period (Brunner and Hen, 1997). These results suggest that 5-HT<sub>1B</sub> receptor may have a role in inhibiting aggressive and impulsive behaviors, although the genetic deletion and pharmacological blockade of 5-HT<sub>1B</sub> result in opposite outcomes.

Several polymorphisms have been reported in the 5-HT<sub>1B</sub> gene; SNPs consisting of G861C and C129T have been the most commonly investigated. Both SNPs are non-synonymous transversions, which do not affect the amino acid structure of the 5-HT<sub>1B</sub> receptor (Lappalainen *et al.*, 1995; Huang *et al.*, 1999). More than 80 percent of individuals in the general population have the combination of C129 and G861, and 5-HT<sub>1B</sub> receptor binding in *post-mortem* human brain was 20 percent lower in C129/G861 genotypes compared to T129/C861 genotypes (Huang *et al.*, 1999). Lappalainen *et al.* (1998) examined the linkage of 5-HT<sub>1B</sub> with alcoholism and antisocial personality disorder, and G861C polymorphism had significant linkage with antisocial alcoholism in two groups. Specifically, C861, the SNP with higher 5-HT<sub>1B</sub> receptor expression, was related to antisocial behavior in alcoholics. However, these associations between the 5-HT<sub>1B</sub> polymorphisms (G861C, G261T or C129T) and aggression/antisocial behavior have not been seen in other studies in humans (Huang *et al.*, 1999; Kranzler *et al.*, 2002; Sinha *et al.*, 2003) or in dogs (van den Berg *et al.*, 2008). Linkage analysis of the other SNP in the 5'UTR region of the 5-HT<sub>1B</sub> gene, A161T, found a significant relationship between this SNP and the history of aggression in subjects who committed suicide (Zouk *et al.*, 2007). Individuals with the T161 locus had higher levels of lifetime aggressive behaviors. T161 polymorphism had reduced transcriptional activity (Sun *et al.*, 2002), and thus lower 5-HT<sub>1B</sub> receptor expression may be related to lifetime aggression in suicidal victims.

### 5-HT<sub>2</sub> receptors and aggression

#### Pharmacology of 5-HT<sub>2</sub> receptors and aggression

Atypical antipsychotic agents (e.g., risperidone) with significant antagonist action at 5-HT<sub>2A</sub> receptors have been successfully used to reduce aggressive behaviors in patients of varying ages and with a wide range of diagnoses, such as depression, schizophrenia, dementia and mental retardation, and post-traumatic stress disorder (Czobor *et al.*, 1995; Buckley *et al.*, 1997; Fava, 1997; De Deyn *et al.*, 1999; Keck *et al.*, 2000; Buitelaar *et al.*, 2001; Zarcone *et al.*, 2001). In animal models, risperidone decreases aggressive behaviors but has been shown to concomitantly reduce mobility (Rodriguez-Arias *et al.*, 1998). 5-HT<sub>2A</sub> specific antagonists, such as ketanserin, ritanserin and MDL 100907, reduced aggressive behavior in monoamine oxidase A (MAOA)-deficient mice (Shih *et al.*, 1999) and in socially isolated mice (White *et al.*, 1991; Sakaue *et al.*, 2002).

DOI and other substituted phenylisopropylamines, agonists that act at both 5-HT<sub>2A</sub> and 5-HT<sub>2C</sub> receptors, also

reduce aggressive behavior in several species, including flies, amphibians, mice and rats (Sanchez *et al.*, 1993; Bonson *et al.*, 1994; de Almeida and Lucion, 1994; Muehlenkamp *et al.*, 1995; Olivier *et al.*, 1995; Ten Eyck, 2008b; Johnson *et al.*, 2009). However, similar to 5-HT<sub>1A</sub> agonists, the effects of 5-HT<sub>2</sub> ligands are not behaviorally specific and are accompanied by sedative effects at the doses that exert anti-aggressive effects. Local administration of 5-HT<sub>2A/2C</sub> agonist into periaqueductal gray (PAG) reduced maternal aggression in rats (de Almeida *et al.*, 2005), whereas microinjections into the medial hypothalamus and also into the PAG increased defensive hissing in cats (Shaikh *et al.*, 1997; Hassanain *et al.*, 2003; Figure 4). This latter effect is likely related to the role of 5-HT<sub>2A/2C</sub> receptors in anxiety-like behavior (Lucki and Wieland, 1990; Nogueira and Graeff, 1995). The development of more selectively acting pharmacological tools will allow a more adequate differentiation of 5-HT<sub>2</sub> receptor subtypes. These novel tools promise to dissociate the anti-aggressive and sedative effects.

#### Genetics of 5-HT<sub>2</sub> receptors and aggression

Platelet 5-HT<sub>2A</sub> receptor binding is increased in personality disorder patients and in a psychiatric population with greater lifetime aggression scores (McBride *et al.*, 1994; Coccaro *et al.*, 1997d). In *post-mortem* brains, lifetime aggression was positively correlated with prefrontal 5-HT<sub>2A</sub> receptor binding in suicide victims (Oquendo *et al.*, 2006). Therefore, it is possible that polymorphisms that affect the level of expression of 5-HT<sub>2A</sub> receptors can be associated with self-directed aggression. In some samples, significant linkage was found between polymorphisms in the 5-HT<sub>2A</sub> receptors, T102C, A1438G and His452Tyr, and aggressive-impulsive trait or adolescent-onset antisocial behavior in humans (Bjork *et al.*, 2002; Assal *et al.*, 2004; Nomura *et al.*, 2006; Burt and Mikolaiewski, 2008). However, others have reported no such relation between aggression and 5-HT<sub>2A</sub> polymorphisms (Khait *et al.*, 2005; Van den Berg *et al.*, 2008). Again, the success with pharmacotherapeutic management of aggressive patients using compounds with affinity for 5-HT<sub>2A</sub> receptors would suggest that violence-prone individuals may be characterized by distinctive 5-HT polymorphisms.

#### Summary for 5-HT receptors and aggression

Genetic studies have shown that associations between aggressive behavior and polymorphisms of 5-HT<sub>1A</sub>, 5-HT<sub>1B</sub> and 5-HT<sub>2A</sub> receptor genes failed to have a clear-cut pattern of results compared to relatively consistent pharmacological data. It may be important to

determine where in the brain the gene expression is changed by the polymorphisms. Behavioral pharmacological studies reveal consistent anti-aggressive effects of 5-HT<sub>1A</sub>, 5-HT<sub>1B</sub> and 5-HT<sub>2A</sub> receptor agonists, which are accompanied, to different extents, by non-specific effects. Novel pharmacological tools promote 5-HT<sub>1B</sub> as a promising target for serenic drugs, despite the fact that these drugs are not currently used in clinical settings. Agonist microinjection experiments further reveal that the role of these receptors in aggressive behavior differs depending on the brain areas targeted. It should be kept in mind that pharmacological findings modulate *phasic* 5-HT activity, while genetic findings from gene knock-out or polymorphisms reflect *trait* characteristics of 5-HT function.

### 5-HT transporters (5-HTT) and aggression

Serotonin transporters are uptake molecules that are responsible for tuning tonic and phasic levels of synaptic 5-HT in the brain in addition to peripheral 5-HT activity.

### Pharmacology of 5-HTT and aggression

Blocking serotonin transporter molecules is effective in reducing and preventing aggressive behavior in humans and animals, due to increased brain 5-HT levels. Clinically, blocking 5-HT transporters with the administration of selective serotonin reuptake inhibitors (SSRIs) reduces aggressive outbursts and violent behavior in psychiatric patients (Coccaro and Kavoussi, 1997; Reist *et al.*, 2003; Bond, 2005; Barkan *et al.*, 2006; Blader, 2006). Similarly to the observed delay in therapeutic effects of SSRIs in the treatment of mood disorders, aggression-reducing effects of SSRIs are usually observed after chronic treatment (>3 weeks). For example, New *et al.* (2004) reported that chronic treatment with fluoxetine significantly reduced aggressive behavior in patients with borderline personality disorders, and normalized prefrontal cortical metabolic activity as assessed by PET (positron emission tomography). Overall, most evidence shows that SSRIs have a beneficial impact in clinical populations that present violent outbursts (Walsh and Dinan, 2001). However, there are occasional reports that SSRIs may facilitate aggressivity and suicidal behavior, and the causes for these unusual outcomes remain to be determined (Troisi *et al.*, 1995; Spigset, 1999).

In animal models, both acute and chronic treatment with SSRIs can dose-dependently reduce aggressive behavior (Olivier *et al.*, 1989; Delville *et al.*, 1996; Pinna *et al.*, 2003; Carrillo *et al.*, 2009). Acute administration

of several SSRIs, such as fluoxetine, fluvoxamine and sertraline, reduces aggression in different contexts and species, including mice, rats and non-human primates (Delville *et al.*, 1996; Fuller, 1996; Cutler *et al.*, 1997; Ferris *et al.*, 1997; Sanchez and Meier, 1997; Fairbanks *et al.*, 2001; Ho *et al.*, 2001). Fewer studies used chronic administration of SSRIs in rodents, which would translate more readily to the clinical treatment that produces anti-aggressive effects in humans (see, for example, Mitchell and Redfern, 1997; Delini-Stula and Vassout, 1981). Interestingly, in placid laboratory rats that do not engage in any aggressive behavior, chronic SSRI treatment restores competent agonistic behavior (Mitchell *et al.*, 1991; Mitchell and Redfern, 1992; Mitchell, 2005). On the other hand, escalated levels of aggression induced by a moderate dose of alcohol were completely prevented during the course of 3 weeks of daily treatment with a highly selective SSRI, citalopram (Figure 5; Caldwell and Miczek, 2008). Baseline levels of aggression were also modestly reduced in those conditions. Thus, the outcomes of chronic SSRI treatment seem to vary depending on the type of aggression (species-typical vs escalated levels) and social context of the animals. Anti-aggressive effects of SSRIs are more prominent in conditions of augmented,

**Figure 5** Effects of repeated, twice daily administration of the SSRI citalopram (10mg/kg, i.p.) on aggressive behavior in mice after drinking 1.0g/kg alcohol in operant self-administration panels. Frequency of aggressive acts ( $\pm$ SEM) is defined as sum of attack bites, threats, pursuits and tail rattles, and was analyzed in 5-minute confrontations against a male intruder, during the course of 4 weeks of citalopram (or saline control) treatment. + symbols represent differences from baseline (+ +  $P < 0.01$ ; + + +  $P < 0.001$ ); \* symbols represent group (citalopram vs saline-control) differences (\*\* $P < 0.01$ ; \*\*\* $P < 0.001$ ). exaggerated aggressive behavior such as those promoted by alcohol (Caldwell and Miczek, 2008).

In support of the 5-HT deficiency hypothesis, acute administration, as well as chronic infusion, of citalopram (or the more potent and selective isomer escitalopram) both elevate extracellular levels of 5-HT in the prefrontal cortex of rats, suggesting increased cortical 5-HT as a putative therapeutic mechanism for SSRIs' effects on aggression and other mood disorders (Ceglia *et al.*, 2004). It is also possible that the anti-aggressive effects of another SSRI, fluoxetine, are primarily mediated by actions on neurosteroids and GABA transmission, and only secondarily via 5-HT (Pinna *et al.*, 2003, 2006). Several neuroadaptations are reported to occur in the 5-HT system as a result of chronic treatment with SSRIs. These neuroadaptations may include changes in serotonin transporter gene expression, binding and reuptake function in the hippocampus and raphe regions (Piñeyro *et al.*, 1994; Benmansour *et al.*, 1999), and 5-HT<sub>1A</sub> auto-receptor desensitization (Blier and de Montigny, 1998; Ceglia *et al.*, 2004). These observations suggest that long-term effects of SSRIs possibly recruit other pre- and postsynaptic downstream mechanisms (e.g., 5-HT receptor-mediated signaling) for their therapeutic effects, rather than just transiently increasing 5-HT synaptic availability.

### **Genetics of 5-HTT and aggressive behavior**

A variation in the length of the 5'-flanking transcriptional control region (promoter) of the 5-HTT gene (the serotonin-transporter-gene-linked polymorphic region; 5-HTTLPR) has been identified in humans (Heils *et al.*, 1996), great apes and rhesus monkeys (Lesch *et al.*, 1997). This variation affects the transcriptional activity of the 5-HTT gene, and the short length (*s*) allele reduces 5-HTT expression *in vitro* and lowers prolactin response to clomipramine in humans, which reflects reduced 5-HT function, compared to the long-length (*l/l*) homozygote (Heils *et al.*, 1995; Lesch *et al.*, 1996; Whale *et al.*, 2000). An association study in humans showed that individuals with one or two copies of the *s* allele (*s/s*, *s/l*) were characterized by higher anxiety, depression, hostility and aggression, and lower agreeableness, than *l/l* homozygotes in both sexes (Lesch *et al.*, 2000). Higher frequency of the *s* allele was observed in alcoholics accompanied by impulsivity and antisocial behaviors (type 2 alcoholism) compared to alcoholics without antisocial behavior (type 1) or healthy controls (Hallikainen *et al.*, 1999). Consistent with the human polymorphism, rhesus monkeys that possess the *s* allele engaged in higher rates of aggressive behaviors compared to *l/l* individuals (Lesch and Merschdorf, 2000; Jarrell *et al.*, 2008).

Again, a genotype–environment interaction can be found in 5-HTT polymorphism. Rhesus monkeys with the *s* allele had lower levels of 5-hydroxyindoleacetic acid (5HIAA) in CSF than *l/l* individuals when they were reared without their mother (peer-reared). This difference disappeared under the mother-rearing condition (Bennett *et al.*, 2002). Peer-reared monkeys showed increased aggression-related behavior as well as altered CSF 5HIAA levels (Kraemer *et al.*, 1989; Higley *et al.*, 1991). In humans, higher suicide ideations or attempts were observed in the individuals carrying the *s* allele than in *l/l* homozygotes when they encountered a number of stressful life events, but not in less stressful situations (Caspi *et al.*, 2003). Therefore, it is possible that individuals with the *s* allele are more vulnerable to the stressful challenges, and subsequently escalate their aggressive behaviors towards others and themselves. However, the effect of the *s* allele on aggression differed among sexes (Cadoret *et al.*, 2003) and even cultures (Baca-Garcia *et al.*, 2004).

Seemingly contrary results were observed in mice with a deletion of the 5-HTT gene (Slc6a4). Homozygote and heterozygote 5-HTT knockout mice on a C57BL/6J background showed fewer attack bites and longer latencies to start fighting relative to wild-type mice in the resident–intruder test (Holmes *et al.*, 2002). 5-HTT knockout mice have lower 5-HT uptake and higher extracellular 5-HT concentrations in the forebrain compared to wild types (Mathews, 2004). 5-HTT knockout mice underwent changes in more than 50 phenotypes, including morphological, physiological, sensory and behavioral functions (Murphy and Lesch, 2008), and thus those pleiotropic changes of other phenotypes may contribute to the reduction of aggressive behaviors in these mice.

### **Summary for 5-HTT and aggression**

Consistent anti-aggressive effects of SSRI treatment among several species strongly suggest that the serotonin transporter is a promising therapeutic target for the management of impulsive, escalated aggression (for review, see Carrillo *et al.*, 2009). More studies are required to determine the precise neurobiological mechanisms recruited for the anti-aggressive effects of SSRIs to emerge, especially as a result of chronic treatment that induces pre- and postsynaptic neuroadaptive processes. The genetic studies in human and non-human primates also suggest 5-HTT polymorphisms (short allele) as a risk factor for violent traits, which seem to be particularly relevant in combination with environmental stress. Results from transgenic mice lacking 5-HTT are more difficult to interpret due to the wide variety of behavioral functions that are affected by the genetic manipulation.

## Monoamine oxidase A (MAOA) and aggression

MAOA, an enzyme that metabolizes monoamine neurotransmitters including norepinephrine (NE), dopamine (DA) and 5-HT, plays a major role in modulating the synaptic availability of 5-HT and other amines.

### Pharmacology of MAOA and aggression

Inhibition of MAOA reduces the oxidative metabolism of monoamines, thus presumably increasing the availability of 5-HT and other monoamines in the brain. Inhibitors of MAOA have been clinically used as first-generation antidepressants, especially in cases that are resistant to treatment with tricyclic antidepressants or SSRIs. Clorgyline was one of the initial selective MAOA inhibitors, but its irreversible inhibition of the enzyme posed serious side effects. More recent developments generated drugs such as moclobemide, a reversible inhibitor of clinical use. Despite the early importance of MAO inhibitors as antidepressants, there have been only a few preclinical studies that systematically evaluated the effects of MAO inhibitors on aggression (Miczek, 1987). For the most part, non-selective inhibitors of both MAOA and MAOB (e.g., phenelzine, isocarboxazid, tranylcypromine) show acute anti-aggressive effects in doses that also promote alterations in motor and other non-aggressive behaviors (DaVanzo *et al.*, 1966; Valzelli *et al.*, 1967; Welch and Welch, 1968; Sofia, 1969). Clinically, non-selective MAO inhibitors or selective MAOB inhibitors can be useful in the pharmacological management of personality disorders that include impulsive aggression and suicidal tendencies as important symptoms, but they are accompanied by an unfavorable profile of side effects (Hollander, 1999; Raj, 2004).

### Genetics of MAOA and aggression

The gene for MAOA was the first candidate identified as a determinant in the susceptibility for aggression in humans. Brunner and colleagues (1993a) identified a large Dutch family with a syndrome of borderline mental retardation and dysregulation of impulsive aggression. All affected males showed aggressive outbursts, and some exhibited sexually aberrant behavior, attempted murder and arson. Linkage and sequence analyses showed that all affected males in this family possessed one missense mutation in the MAOA gene on the X chromosome, so that MAOA function was completely disturbed (Brunner *et al.*, 1993a). The affected males had higher serotonin

and lower metabolites of NE, DA and 5-HT in the urine, whereas they had normal MAOB activity (Brunner *et al.*, 1993b). MAOA also is of significance in the probability of fighting in animals. Male mice with a disrupted MAOA gene on either C3H/He or 129Sv background expression showed escalated aggressive behaviors compared to wild types, as is evident by skin wounds among the cage-mates and a short latency to initiating attacks in the resident-intruder test (Cases *et al.*, 1995; Scott *et al.*, 2008). MAOA-deficient mice also showed a large increase in 5-HT and NE, and a subtle DA elevation, in the brain and liver (Cases *et al.*, 1995; Kim *et al.*, 1997). It is likely that the change of 5-HT function is the cause of the behavioral changes in the MAOA-deficient mice. Ketanserin and MDL100907, antagonists that preferentially bind to 5-HT<sub>2A</sub> receptors, blocked the escalated aggression in the MAOA mutant mice (Shih *et al.*, 1999). Depletion of 5-HT by pCPA during the early developmental stage improved some behavioral and brain structural abnormality in the MAOA-deficient mice (Cases *et al.*, 1995, 1996).

Polymorphisms in the MAOA gene can alter MAOA activity and thus modulate catecholaminergic and serotonergic function. Variable-number tandem repeat (VNTR) polymorphism, which exists on the upstream region of the MAOA gene, regulates MAOA expression depending on the number of repeats: alleles with 3.5 or 4 repeats have 2- to 10-times higher transcription than 3 or 5 repeat alleles *in vitro* (Sabol *et al.*, 1998; Denney *et al.*, 1999). A prominent interaction between MAOA genotype and environment (maltreatment) on aggressive behavior has been reported (Figure 6). Under a stressful rearing environment, such as abuse or neglect, or with traumatic life events in the first 15 years of their lives, individuals with low MAOA expression (MAOA-L) polymorphisms showed a higher propensity for criminal arrest, a violent history and adolescent conduct disorder, and also higher aggressive disposition, in the self-report questionnaire compared to individuals with higher MAOA expression (MAOA-H) or MAOA-L individuals without abuse (Caspi *et al.*, 2002; Foley *et al.*, 2004; Kim-Cohen *et al.*, 2006; Widom and Brzustowicz, 2006; Frazzetto *et al.*, 2007; Weder *et al.*, 2009). If rearing environments were lumped together, the effect of the MAOA genotype disappeared (Fresan *et al.*, 2007) or sometimes MAOA-H individuals reported higher aggression using interviews and questionnaires (Manuck *et al.*, 2000, 2002). Therefore, individuals with the MAOA-L allele are vulnerable to environmental factors and show a high propensity to engage in aggressive behaviors only when they are in a stressful environment. These findings are consistent in males, but not in females (Sjoberg *et al.*, 2007). Rhesus monkeys also have a repeat length variation polymorphism (rhMAOA-LPR)

**Figure 6** Means on the composite index of antisocial behavior as a function of MAOA activity and a childhood history of maltreatment. MAOA activity is the gene expression level associated with allelic variants of the functional promoter polymorphism, grouped into low and high activity; childhood maltreatment is grouped into three categories of increasing severity. The antisocial behavior composite is standardized (z score) to  $M = 0$  and  $SD = 1$ ; group differences are interpretable in SD unit differences (d). Copyright 2002 by The American Association for the Advancement of Science. Reprinted with permission from Caspi *et al.* (2002).

in the MAOA gene. Monkeys with a low-activity allele exhibited higher aggressive behavior and tended to attain higher dominance rank when they were reared by their mother. In contrast, when they were reared separately from their parents (peer-reared), monkeys with the low-activity allele engaged in less aggressive behavior (Newman *et al.*, 2005). This inhibition of aggression has been attributed to increased fear and anxiety in peer-reared monkeys (Higley and Suomi, 1986).

Neuroimaging studies have indicated pronounced differences in the volume and activity of limbic system and neocortical areas between individuals with MAOA-L and MAOA-H (see Buckholtz and Meyer-Lindenberg, 2008, for review). fMRI analysis in healthy human volunteers showed that MAOA-L males had smaller limbic and orbito-frontal volumes, and higher activity in amygdala and hippocampus during aversive recall (Meyer-Lindenberg *et al.*, 2006), which may be related to violent behavior in these individuals. Alia-Klein *et al.* (2008) reported that lower MAOA activity in cortical and subcortical brain areas is associated with high aggression, measured by self-report questionnaire, independent from MAOA polymorphism.

### Summary for MAOA and aggression

Strong evidence for a role of MAOA in aggressive behaviors is supported by genetic studies of a deleterious mutation of the MAOA gene in humans and knockout mice.

In contrast to the serotonin deficiency hypothesis, these results suggest that chronically increased 5-HT levels due to reduced MAOA function (*trait-like* change) may promote escalated aggressive displays. Gene polymorphism studies further revealed critical gene–environment interactions. Individuals with low MAOA activity and a history of early life maltreatment are particularly prone to engage in violent behavior. Conversely, pharmacological inhibition of MAO promotes phasic changes of 5-HT (*state-like* change), and generally reduces aggressive behaviors in doses that produce non-specific behavioral effects. It would be of interest to study more selective MAOA inhibitors and how they affect different types of aggression in rodents.

### Other molecules that directly or indirectly affect 5-HT pathways and aggression

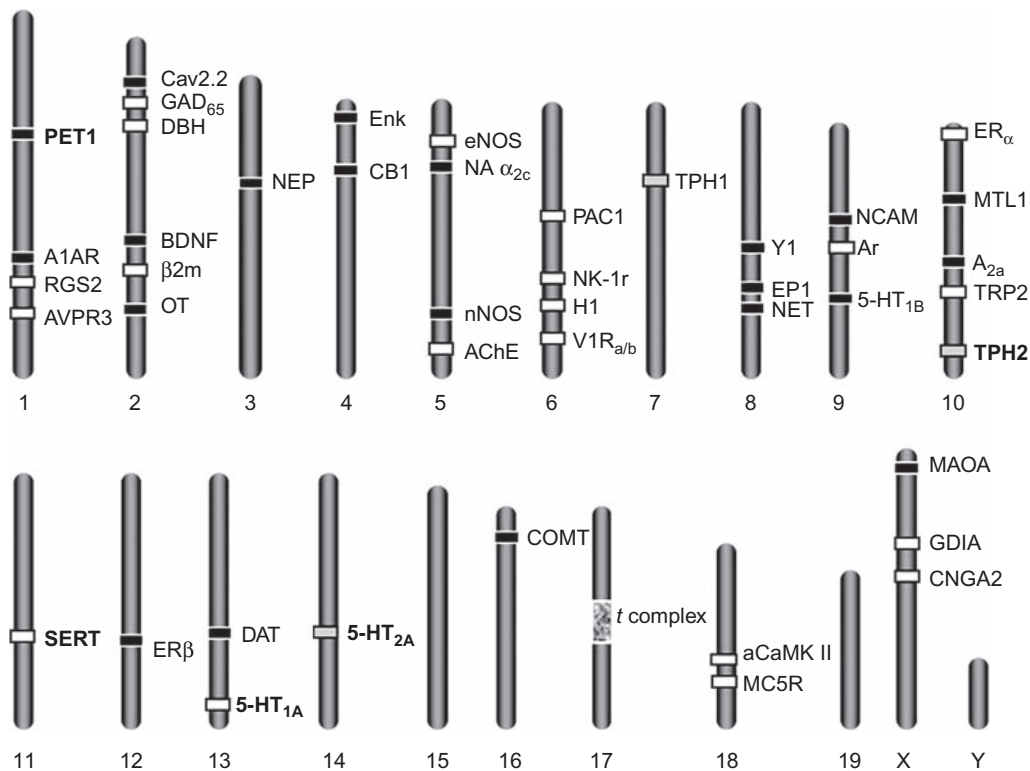

Here we will briefly discuss selected molecules that indirectly affect 5-HTergic pathways and modulate aggressive behaviors, based mainly on findings from gene knockout mouse studies, as summarized in Figure 7.

#### *Pet-1 (also known as Fev)*

Pet-1, one of the transcription factors, is specifically expressed in the raphe 5-HT neurons, and has a critical role in 5-HT neuronal development. Deletion of Pet-1 expression reduced 5-HT levels in the forebrain, and also depleted expression of TPH, 5-HTT and the vesicular monoamine transporter 2 (Vmat2). In the resident–intruder test, Pet-1 knockout mice (Pet-1<sup>-/-</sup>) on a mixed C57BL/6J and 129Sv background engage in higher frequency and intensity of attacks toward a conspecific male (Hendricks *et al.*, 2003). These increases in aggressive behavior in Pet-1<sup>-/-</sup> mice are embedded in broad behavioral disruptions that extend to maternal and anxiety-like behaviors (Hendricks *et al.*, 2003; Lerch-Haner *et al.*, 2008), and it is possible that those other behavioral changes promote aggressive behaviors. Because general gene knockouts can affect an animal's development and induce compensatory changes of other gene expressions, investigation using conditional knockout of Pet-1 expression at discrete developmental stages promises to give more insight into the role of this gene in more specific behaviors.

#### *Brain-derived neurotrophic factor (BDNF)*

BDNF has several important roles in the neuron, including neuronal survival, development, differentiation and plasticity. Mice with decreased BDNF expression, including

**Figure 7** Genes/alleles implicated in mouse aggression. This figure shows representations of mouse chromosomes (19 autosomes + sex chromosomes) and the approximate location of genes related to aggressive behaviors. Genes related to 5-HT pathways are highlighted as bold. Genes that have been knocked out in mice and engendered heightened (black-filled bars) or suppressed (open bars) levels of aggressive behaviors are also indicated. No knockout mice data were available for some 5-HT related genes (gray bars). The *t* region and Y chromosome are also indicated because of the prominent effect on male aggressive behavior (see Miczek *et al.*, 2001, for review). Abbreviations and references for knockout studies: 5-HT<sub>1A</sub>, serotonin receptor 1A (Zhuang *et al.*, 1999); 5-HT<sub>1B</sub>, serotonin receptor 1B (Saudou *et al.*, 1994); A1AR, adenosine receptor A1 (Gimenez-Llort *et al.*, 2002); A<sub>2a</sub>, adenosine receptor 2A (Ledent *et al.*, 1997); AChE, acetylcholinesterase (Duysen *et al.*, 2002); αCaMK II, alpha-calcium-calmodulin kinase II (Chen *et al.*, 1994); Ar, aromatase (Matsumoto *et al.*, 2003); AVPR3, arginine vasopressin 1B receptor (Wersinger *et al.*, 2002); β2m, beta2-microglobulin (Loconto *et al.*, 2003); Cav2.2, α1B subunit (Young *et al.*, 2002) of N-type Ca<sup>2+</sup> channels (Kim *et al.*, 2009); CB1, cannabinoid receptor 1 (Martin *et al.*, 2002); CNGA2, cyclic nucleotide gated channel alpha 2 (Mandiyar *et al.*, 2005); COMT, catechol-O-methyltransferase (Gogos *et al.*, 1998); DAT, dopamine transporter (Rodriguez *et al.*, 2004); DBH, dopamine beta hydroxylase (Marino *et al.*, 2005); eNOS, endothelial nitric oxide synthase (Demas *et al.*, 1999); ENK, enkephalin (Konig *et al.*, 1996); EP1, prostaglandin E receptor 1 (Matsuoka *et al.*, 2005); ERα, estrogen receptor alpha (Ogawa *et al.*, 1998); ERβ, estrogen receptor beta (Ogawa *et al.*, 1999); GAD65, glutamic acid decarboxylase (65 amino acids) (Stork *et al.*, 2000); GDIA, guanosine diphosphate (GDP) dissociation inhibitor 1 (D'Adamo *et al.*, 2002); H1, histamine receptor 1 (Yanai *et al.*, 1998); MAOA, monoamine oxidase A (Cases *et al.*, 1995); MC5R, melanocortin-5 receptor (Morgan and Cone, 2006); MTL1, nuclear receptor subfamily 2, group E, member 1 (aka 'FIERCE') (Young *et al.*, 2002); Naα<sub>2c</sub>, adrenergic alpha receptor 2C (Sallinen *et al.*, 1998); NCAM, neural cell adhesion molecule (Stork *et al.*, 1997); NEP, neutral endopeptidase (Fischer *et al.*, 2000); NET, norepinephrine transporter (Haller *et al.*, 2002); NK-1r, neurokinin receptor 1 (De Felipe *et al.*, 1998); nNOS, neuronal nitric oxide synthase (Nelson *et al.*, 1995); OT, oxytocin (Winslow *et al.*, 2000); PAC1, adenylate cyclase activating polypeptide 1 receptor 1 (Nicot *et al.*, 2004); PET-1, ETS (E26 transformation specific) domain transcription factor (Hendricks *et al.*, 2003); RGS2, regulator of G protein signaling (Oliveira-dos-Santos *et al.*, 2000); SERT, serotonin transporter (Holmes *et al.*, 2002); Trp2, transient receptor potential family 2 (Stowers *et al.*, 2002); V1R<sub>a/b</sub>, a cluster of vomeronasal receptor genes located on chromosome six, V1ra1–9 and V1rb1–4, 7–9 (Del Punta *et al.*, 2002); Y1, neuropeptide Y receptor 1 (Karl *et al.*, 2004).

knockout (BDNF<sup>+/-</sup>) and conditional knockout (BDNF<sup>2L/ILNes-cre</sup> and BDNF<sup>2L/2LCK-cre</sup>) mice with a mixed background all showed increased inter-male aggression (Lyons *et al.*, 1999; Chan *et al.*, 2006). Fluoxetine reduced their heightened aggressive behavior (Lyons *et al.*, 1999). All mutants changed 5-HT<sub>2A</sub> receptor expression; however,

BDNF<sup>+/-</sup> mice showed increased 5-HT<sub>2A</sub> expression in the lateral frontal cortex and hypothalamus (Lyons *et al.*, 1999), whereas BDNF<sup>2L/ILNes-cre</sup> and BDNF<sup>2L/2LCK-cre</sup> mice exhibited reduced 5-HT<sub>2A</sub> receptor expression in the prefrontal cortex (Chan *et al.*, 2006; Rios *et al.*, 2006). An SNP in the BDNF gene, Val66Met, has attracted strong

interest because of its association with mood disorders and hippocampal function in humans (Neves-Pereira *et al.*, 2002; Egan *et al.*, 2003). Although this polymorphism is found only in humans, an animal model was established by inserting a BDNF<sup>Met</sup> knock-in allele in the mouse (Chen *et al.*, 2006). This animal also showed increased aggressive behavior, and changed the response to SSRI treatment (Chen *et al.*, 2006). In contrast to the consistent results on aggressive behavior among BDNF mutant mice, studies on polymorphisms of the BDNF gene in aggressive behavior in humans remain to be resolved. No association was observed between Val66Met polymorphism and proneness to violence in a Chinese male sample (Tsai *et al.*, 2005). Other SNPs in the BDNF gene may be associated with high impulsivity in children with ADHD (Oades *et al.*, 2008).

### Nitric oxide

Nitric oxide, a free radical gas which diffuses across membranes, is involved in several cellular functions (for review, see Calabrese *et al.*, 2007). Mice lacking neuronal nitric oxide synthase (nNOS<sup>-/-</sup>) on a mixed C57BL/6J and 129Sv background show various deficits in their physiological development and also behavior (Huang *et al.*, 1993). nNOS<sup>-/-</sup> males, but not females, showed a higher duration of aggressive behavior, and also displayed much fewer submissive postures compared to wild types (Nelson *et al.*, 1995). Serotonergic dysfunction was observed in the nNOS<sup>-/-</sup> mice, specifically reduced 5-HT turnover in the brain and deficient 5-HT<sub>1A</sub> and 5-HT<sub>1B</sub> receptor function (Chiavegatto *et al.*, 2001). Escalated aggression in the nNOS<sup>-/-</sup> mice was rescued by 5-HTP treatment, which increased 5-HT level and turnover. These findings point to an important role of nitric oxide for the normal 5-HT function, and thus increased aggression in nNOS<sup>-/-</sup> mice may be induced by changing 5-HT activity.

### Neuropeptide Y (NPY)

NPY primarily controls food intake, energy balance, and metabolic regulation (Herzog, 2003). This molecule, which is critical for energy homeostasis, is also implicated in aggressive behavior (Emeson and Morabito, 2005). Male mice with deleted expression of Y1-receptor (Y1<sup>-/-</sup>) on a mixed C57BL/6-129SvJ background showed obesity and reduced energy homeostasis (Kushi *et al.*, 1998), and also exhibited increased aggressive behaviors in the resident-intruder test (Karl *et al.*, 2004). However, this escalated aggression in Y1<sup>-/-</sup> mice was observed only in the

home-cage but not in the novel environment. This result suggests a specific increase in territorial aggression. Karl *et al.* (2004) provided evidence that altered 5-HT function underlies the aggressive behavior of Y1<sup>-/-</sup> mice. TPH mRNA expression in the raphe nuclei was reduced in the Y1<sup>-/-</sup> mice. In addition, 5-HT<sub>1A</sub> agonist treatment reduced escalated aggression in Y1<sup>-/-</sup> mice.

### α-Calcium-calmodulin kinase II (α-CaMKII)

α-CaMKII is a neural-specific enzyme, and has been shown to be involved in long-term potentiation (LTP) (Silva *et al.*, 1992). Heterozygotes of α-CaMK II knock-out mice on a mixed C57BL/6-129/OU-BALB/c background showed escalated defensive aggression but not offensive aggression (Chen *et al.*, 1994). In the resident-intruder test, resident α-CaMKII heterozygotes showed similar aggressive behavior to that of wild-type mice. In contrast, when the mutant was tested as an intruder, it exhibited high defensive reactions toward the resident. Reduced 5-HT release was observed in the dorsal raphe of the α-CaMKII mutant *in vitro*, and thus the changed 5-HT function may be associated with defensive aggression in this mouse.

### General conclusions

Across different species, a critical role for serotonin in aggressive, violent behaviors is supported by a wide variety of observations and experimental approaches. Starting with the 'serotonin deficiency hypothesis', which stated that lower 5-HT function was inversely correlated with an increased risk to engage in impulsive aggressive outbursts, new developments have revealed the complexity of the serotonin-aggression link. Such complexity can be reflected by the intrinsically different types of aggression, particularly when comparing normative, species-typical patterns of aggressive behavior with fundamentally different types of escalated, pathological aggression. From clinical and preclinical studies, most evidence suggests that a serotonin dysfunction is characteristic of individuals presenting impulsive, hostile and violent behavior. These individuals may particularly benefit from pharmacological treatments aimed at inhibiting 5-HT transporters (using SSRIs such as fluoxetine or citalopram), or activating 5-HT<sub>1A</sub> (buspirone) or 5-HT<sub>2A</sub> receptors (risperidone). Acutely, these drugs induce *phasic* changes in 5-HT function that are associated to their anti-aggressive effects (i.e., *state* changes). On the other hand, chronic treatment with these anti-aggressive compounds may promote neuroadaptive changes in 5-HT function that are

associated with the emergence of therapeutic effects (i.e., autoreceptor desensitization). The critical anti-aggressive effects of 5-HT receptor agonists appear to be mediated by both pre- and post-synaptic sites of action. The use of drug microinjection techniques into discrete brain areas (terminals vs. soma), together with the development of novel pharmacological tools that specifically target receptor subpopulations, may help to define these mechanisms more adequately. Furthermore, promising and reasonably selective anti-aggressive effects have been obtained in preclinical studies using 5-HT<sub>1B</sub> receptor agonists, and are awaiting clinical validation.

While it is clear that multiple genes contribute in the determination of *traits* for an aggressive phenotype, it is remarkable that in several cases a gene–environment interaction is required for increased propensity to engage in violent outbursts, as observed with MAOA and 5-HTT polymorphisms. In a recent study, Passamonti *et al.* (2008) showed interactions between 5-HTT and MAOA polymorphisms, and those interactions exerted stronger effects on the activity of the anterior cingulate cortex, one of the brain areas implicated in impulsivity and aggression. Many other genes may have subtle effects on aggressive phenotypes, and it is possible that those genes have complex epistatic interactions from which emerge stronger effects (Miczek *et al.*, 2001). In rodents, most genetic studies on aggression make use of conventional knockout techniques in which the expression of a gene is generally deleted in the whole body, affecting all developmental stages and inducing compensatory changes in other genes (trait-like changes). Novel tools, including conditional knockout, viral vector microinfusion, or drug-inducible knockout techniques, can produce transient and local changes in gene expression, enabling the examination of more ‘phasic’ changes in gene expression and how they affect aggressive behavior. The use of these techniques may reduce some discrepancies in the results from genetic and pharmacological studies of 5-HT function in aggression.

In summary, understanding the complex role of 5-HT in aggression requires consideration of multiple factors, including (1) the type of aggressive behavior, its topography and function; (2) the genetic background of the individual and the typical phenotype for this background; (3) the trait characteristics of the human subject or the mouse (e.g., *Mus musculus* is a pugnacious species and many recombinant inbred strains are quite placid); and (4) the situational conditions under which aggressive behaviors have been engaged. By defining the specific characteristics of the individual, the environment and the type of social interaction, the serotonin–aggression link can be further explored, providing new pharmacological and molecular targets for interventions.

# Altered Serotonin Function in Anorexia and Bulimia Nervosa

Vikas Duvvuri<sup>1</sup>, Ursula F. Bailer<sup>1,2</sup> and Walter H. Kaye<sup>\*,1</sup>

<sup>1</sup>University of California San Diego, School of Medicine, Department of Psychiatry, La Jolla, California

<sup>2</sup>Medical University of Vienna, Department of Psychiatry and Psychotherapy, Division of Biological Psychiatry, Vienna, Austria

**Abstract:** Anorexia nervosa (AN) and bulimia nervosa (BN) are related disorders of unknown etiology that most commonly begin during adolescence in women. They are characterized by aberrant patterns of feeding behavior and weight regulation, and deviant attitudes and perceptions toward body weight and shape. In AN, an inexplicable fear of weight gain and unrelenting obsession with being fat, even in the face of increasing emaciation, accounts for a protracted course. BN usually emerges after a period of food restriction, which may or may not have been associated with weight loss. Binge eating is followed either by self-induced vomiting, or by other means of compensation for the excess of ingested food. There is growing acknowledgement that neurobiological vulnerabilities make a substantial contribution to the pathogenesis of AN and BN, suggesting that altered brain serotonin (5-HT) function contributes to dysregulation of appetite, mood, and impulse control. Brain imaging studies, using 5-HT specific ligands, show that disturbances of 5-HT function occur when people are ill, and persist after recovery. It is possible that a trait-related disturbance of 5-HT neuronal modulation predates the onset of AN, and contributes to premorbid symptoms of anxiety, obsessiveness and inhibition. This dysphoric temperament may involve an inherent dysregulation of emotional and reward pathways which also mediates the hedonic aspects of feeding, thus making these individuals vulnerable to disturbed appetitive behaviors. Individuals with AN may discover that reduced dietary intake, by reducing plasma tryptophan availability, is a means by which they can modulate brain 5-HT functional activity and anxious mood. They enter a vicious cycle, because caloric restriction results in a brief respite from dysphoric mood. However, malnutrition and weight loss, in turn, produce alterations in many neuropeptides and monoamine function, which also exaggerates dysphoric mood. Thus, those with AN pursue starvation in an attempt to avoid the dysphoric consequences of eating.

**Keywords:** serotonin, anorexia, bulimia, anxiety, neuroimaging, harm avoidance, impulsivity.

## Introduction

Anorexia nervosa (AN) and bulimia nervosa (BN) are related disorders of unknown etiology that most commonly begin during adolescence in women (*DSM-IV*; Table 1). They are frequently chronic and often disabling conditions that are characterized by aberrant patterns of feeding behavior and weight regulation, and deviant attitudes and perceptions toward body weight and shape. In AN, an inexplicable fear of weight gain and unrelenting obsession with being fat, even in the face of increasing emaciation, accounts for a protracted course. Sequelae include extreme medical and psychological morbidity, and standardized mortality

rates exceeding those of all other psychiatric disorders. BN usually emerges after a period of food restriction, which may or may not have been associated with weight loss. Binge eating is followed by either self-induced vomiting, or by some other means of compensation for the excess of food that is ingested. Although abnormally low body weight is an exclusion criterion for the diagnosis of BN, some 25–30 percent of individuals with BN have a prior history of AN.

Because AN and BN present most often during adolescence in women, they are often theorized to be caused by cultural pressures for thinness (Kaye *et al.*, 2009), since dieting and the pursuit of thinness are common in industrialized countries. Still, AN and BN affect only an estimated 0.3–0.7 percent and 1.5–2.5 percent, respectively, of females in the general population (Hoek *et al.*, 1995), suggesting that an underlying biological predisposition might

**Table 1** *DSM IV* diagnostic criteria for anorexia nervosa and bulimia nervosa

DSM IV, Diagnostic criteria for Anorexia Nervosa	
A	Refusal to maintain body weight at or above a minimally normal weight for age and height (e.g., weight loss leading to maintenance of body weight less than 85% of that expected; or failure to make expected weight gain during period of growth, leading to body weight less than 85% of that expected).
B	Intense fear of gaining weight or becoming fat, even though underweight.
C	Disturbance in the way in which one's body weight or shape is experienced, undue influence of body weight or shape on self-evaluation, or denial of the seriousness of the current low body weight.
D	In postmenarcheal females, amenorrhea, i.e., the absence of at least three consecutive menstrual cycles. (A woman is considered to have amenorrhea if her periods occur only following hormone, e.g., estrogen, administration.)
Specify type:	
<b>Restricting type:</b> during the current episode of anorexia nervosa, the person has not regularly engaged in binge-eating or purging behavior (i.e., self-induced vomiting or the misuse of laxatives, diuretics, or enemas)	
<b>Binge-eating/purging type:</b> during the current episode of anorexia nervosa, the person has regularly engaged in binge-eating or purging behavior (i.e., self-induced vomiting or the misuse of laxatives, diuretics, or enemas)	
DSM IV, Diagnostic criteria for Bulimia Nervosa	
A	Recurrent episodes of binge-eating. An episode of binge-eating is characterized by both of the following <ol style="list-style-type: none"> <li>(1) Eating, in a discrete period of time (e.g., within any 2-hour period), an amount of food that is definitely larger than most people would eat during a similar period of time and under similar circumstances.</li> <li>(2) A sense of lack of control over eating during the episode (e.g., a feeling that one cannot stop eating or control what or how much one is eating)</li> </ol>
B	Recurrent inappropriate compensatory behavior in order to prevent weight gain, such as self-induced vomiting, misuse of laxatives, diuretics, enemas, or other medications; fasting, or excessive exercise.
C	The binge-eating and inappropriate compensatory behaviors occur, on average, at least twice a week for three months.
D	Self-evaluation is unduly influenced by body shape and weight.
E	The disturbance does not occur exclusively during episodes of Anorexia Nervosa.
Type: purging type vs. non-purging type (exercise and fasting to compensate)	
Specify type	
<b>Purging type:</b> during the current episode of Bulimia Nervosa, the person has regularly engaged in self-induced vomiting or the misuse of laxatives, diuretics, or enemas	
<b>Non-purging type:</b> during the current episode of Bulimia Nervosa, the person has used other inappropriate compensatory behaviors, such as fasting or excessive exercise, but has not regularly engaged in self-induced vomiting or the misuse of laxatives, diuretics, or enemas	

play an important role. Indeed, there is clear evidence of AN occurring at least several centuries ago (Treasure and Campbell, 1994). Its stereotypic presentation, substantial heritability, and a developmentally specific age-of-onset distribution further underscore the possibility of contributing biological vulnerabilities.

Considering that transitions between syndromes occur in many individuals, it has been argued that AN and BN share at least some risk and liability factors (Kendler *et al.*, 1991; Schweiger and Fichter, 1997). In fact, AN and BN are cross-transmitted in families (Lilenfeld *et al.*, 1998; Strober *et al.*, 2000). Moreover, there is an increased prevalence of AN and BN as well as subthreshold forms of eating disorders (EDs) in relatives, consistent with the possibility of a continuum of transmitted liability in at-risk families manifesting a broad spectrum of eating disorder phenotypes. Twin studies can differentiate genetic from environmental effects by comparing concordance for a trait, or disorder, between

identical (monozygotic, MZ) and fraternal (dizygotic, DZ) twins. Twin studies of AN and BN suggest that there is an approximately 50–80 percent genetic contribution to liability (Kendler *et al.*, 1991; Bulik *et al.*, 1998, 2006; Klump *et al.*, 2001; Wade *et al.*, 2000) accounted for by additive genetic factors. These heritability estimates are similar to those found in schizophrenia and bipolar disorder, suggesting that AN and BN may be as genetically influenced as disorders traditionally viewed to be biological in nature.

### Clinical symptoms and puzzling behaviors

The *DSM-IV* diagnostic criteria for AN and BN focus on eating behavior and body image distortions. Because of their unusual and prominent nature, these symptoms tend to capture much attention. The pathogenesis of the disturbed eating behaviors is poorly understood (Vitousek and

Manke, 1994; Schweiger and Fichter, 1997). Individuals with AN rarely have complete suppression of appetite, but rather exhibit an ego-syntonic resistance to feeding drives while simultaneously being preoccupied with food and eating rituals to the point of obsession. Individuals with AN severely restrict food intake, particularly fats and carbohydrates, but rarely stop eating completely; instead, they restrict their caloric intake to a few hundred calories a day. They tend to be vegetarians, have monotonous choices in the food they eat, select unusual combinations of foods and flavors, and have ritualized eating behaviors. Similarly, BN is not associated with a primary, pathological increase in appetite; rather, like individuals with AN, individuals with BN have a seemingly relentless drive to restrain their food intake, an extreme fear of weight gain, and often have a distorted view of their actual body shape. Loss of control with overeating in individuals with BN usually occurs intermittently, and typically only some time after the onset of dieting behavior. Restrained eating behavior and dysfunctional cognition relating weight and shape to self-concept are shared by all types of patients with EDs.

AN and BN individuals commonly have clusters of other puzzling symptoms. Excessive exercise and motor restlessness are common in AN (Shroff *et al.*, 2006). While not well studied, excessive exercise is thought to be associated particularly with the purging subtype of AN as well as with a constellation of anxious/obsessional temperaments. Individuals with AN often have resistance to treatment (Halmi *et al.*, 2005). This is in part due to the ego-syntonic nature of the disorder, which is demonstrated by the patient's denial of being underweight and refusal to accept the seriousness of the medical consequences of the disorder. Consequently, it has been difficult to enlist the cooperation of individuals with AN for treatment studies. This, and the fact that psychological/pharmacological strategies effective in other disorders are less so for AN, likely explains the dearth of controlled treatment trials of any kind.

### ***Mood and impulse control***

Individuals with AN and BN have elevated rates of lifetime diagnoses of anxiety and depressive disorders, and obsessive-compulsive disorder (Lilenfeld *et al.*, 1998; Godart *et al.*, 2002, 2007; Kaye *et al.*, 2004a). In addition, individuals with AN and BN are consistently characterized by perfectionism, obsessive-compulsiveness, neuroticism, negative emotionality, harm avoidance, low self-directedness, low cooperativeness, and traits associated with avoidant personality disorder (PD). There are consistent differences that emerge between groups of individuals with ED. Those with restricting-type AN exhibit

high constraint and persistence, low novelty-seeking, constriction of affect and emotional expressiveness, anhedonia and asceticism, and reduced social spontaneity. Individuals with BN are more likely to be of high impulsivity, sensation-seeking, novelty-seeking, and to have traits associated with borderline personality disorder and substance use disorders (Cassin and von Ranson, 2005). Thus, several domains, such as eating, affect and impulse control, are involved in systematic ways in EDs. Specifically, AN is associated with over-control and BN is associated with switches between over-control and under-control, which raises the question of whether there is a concerted disturbance in the modulation of multiple systems.

### ***Neurocognition***

Individuals with AN have an obsessive, perseverative and rigid personality style, and have difficulty shifting sets. While those with AN do well on goal-directed behavior, they have difficulties incorporating feedback and modifying their behavior. For example, they often feel that they should be able to do things perfectly without making mistakes, and they have little appreciation for the fact that mistakes are a normal learning experience. Moreover, they often fail to accurately recognize and incorporate affective and social stimuli in the environment, as confirmed by laboratory tests (Strupp *et al.*, 1986; Kingston *et al.*, 1996). Those who are ill with (ILL) AN and recovered from (REC) AN tend to have delayed set-shifting (Tchanturia *et al.*, 2005), an ability that normally allows for the adaptation of behavior in line with the changing demands of one's environment. Furthermore, individuals with AN have an enhanced ability to pay attention to detail or use a logical/analytic approach, but exhibit worse performance with global strategies (Strupp *et al.*, 1986; Lopez *et al.*, 2007).

### ***State and trait***

It has long been debated whether symptoms in individuals with AN and BN are the cause or consequence of malnutrition. Confounding this understanding is the issue that most studies of symptoms have been done when individuals are ill with an ED. Recent studies have shown that the majority of people with AN and BN exhibit childhood perfectionism, obsessive-compulsive personality patterns, and anxiety, all of which predate the onset of AN and BN (Fairburn *et al.*, 1997; Godart *et al.*, 2002; Anderluh *et al.*, 2003). Moreover, studies done on three continents (Table 2) have shown that in AN and BN individuals with

a lifetime history of an anxiety-disorder diagnosis, the anxiety disorder most often began in childhood before the onset of the ED (Deep *et al.*, 1995; Bulik *et al.*, 1997b, 1997c; Godart *et al.*, 2000). The most common premorbid childhood disorders were OCD and social phobia (Kaye *et al.*, 2004a). In summary, such symptoms may be susceptibility factors that make people vulnerable to developing an ED. Malnutrition tends to exaggerate premorbid behavioral traits, not cause them (Pollice *et al.*, 1997).

It is important to note that such temperament and personality traits persist after recovery from an ED. While a definition of recovery has not been formalized, investigators tend to include people once they have been at a stable and healthy body weight for months or years, are not malnourished, and have not engaged in pathological eating behavior during that period of recovery. Some investigators include a criterion of a normal menstrual cycle, and a minimal duration of recovery, such as 1 year. Investigators (Strober, 1980; Casper, 1990; Srinivasagam *et al.*, 1995; Kaye *et al.*, 1998) have found that women who are long-term recovered from AN and BN have a persistence of anxiety, perfectionism and obsessional behaviors (particularly symmetry, exactness and order). Determining cause and effect is a major methodological confound in this illness. Thus, this chapter will focus on studies that have been done in people who have recovered from AN and BN. The persistence of many alterations after recovery suggests that these may be traits that create a vulnerability to develop an ED, although it is possible these are ‘scars’ caused by the ill state.

### Neurobiology

There is growing acknowledgement that neurobiological vulnerabilities make a substantial contribution to the pathogenesis of AN and BN (Treasure and Campbell,

1994); however, we have little understanding of how such vulnerabilities result in disturbances of brain pathways or which systems are primarily involved. For example, are there disturbances of pathways related to the modulation of feeding behaviors, mood, temperament, obsessiveness or impulse control? Are there primary disturbances of pathways that may modulate some factors related to body proprioception, and thus result in body image distortions? In the past, answering these questions has been thwarted by the inaccessibility of the brain. Technologies capable of characterizing the complexity of brain circuits in humans, such as imaging or genetics, have only recently become available. Still, past studies have been useful in terms of grossly identifying systems that may be involved in ED. Because these technologies could only characterize one molecule at a time, they weren’t able to provide answers to questions about complex interactions and functions.

### Serotonin

Much technology has focused on characterizing the function of monoamines, such as serotonin (5-HT), dopamine (DA) and norepinephrine (NE). In part, this is because many of the medications used to treat psychiatric disorders act on these systems. Although neurotransmission occurs via distinct receptors, these systems have reciprocal interactions, so it is virtually impossible to act on a specific neuronal element without a cascade effect on the two other systems (Tremblay and Blier, 2006).

#### Investigations of serotonin metabolism

Theoretically, 5-HT disturbances could contribute to appetite dysregulation (Blundell, 1984; Leibowitz and Shor-Posner, 1986), anxious and obsessive behaviors, and extremes of impulse control (Soubrie, 1986; Cloninger,

**Table 2** Lifetime and premorbid rates of anxiety disorders

Study	ED	N	Lifetime D	AD before ED
Deep <i>et al.</i> , 1995	AN	24	68%	58%
Bulik <i>et al.</i> , 1997a	AN	68	60%	54%
Bulik <i>et al.</i> , 1997c	BN	116	57%	54%
Godart <i>et al.</i> , 2000	AN	29	83%	62%
Godart <i>et al.</i> , 2000	BN	34	71%	62%
Kaye <i>et al.</i> , 2004a	AN, BN	672	64%	61%
				23% OCD
				13% social phobia

*Abbreviations:* AD, anxiety disorder; AN, anorexia nervosa; BN, bulimia nervosa; ED, eating disorder; Lifetime D, lifetime disorder.

1987; Higley and Linnoila, 1997; Lucki, 1998; Mann, 1999). Considerable evidence suggests that disturbances of monoamine function occur when people are ill with ED, and persist after recovery from AN and BN (Brewerton *et al.*, 1990; Jimerson *et al.*, 1997; Walsh and Devlin, 1998; Steiger *et al.*, 2001a; Kaye *et al.*, 2004b).

ILL AN subjects have a significant reduction in 5-hydroxyindoleacetic acid (5-HIAA) in their cerebrospinal fluid (CSF) compared to control subjects (CW), whereas CSF 5-HIAA levels are normal in ILL BN (Jimerson *et al.*, 1992; Kaye *et al.*, 1984, 1990, 1991a, 1998). In comparison, REC AN and BN subjects have higher than normal concentrations of CSF 5-HIAA, which is about 50 percent greater than CSF 5-HIAA levels found in the ILL state. While CSF levels have been found to reflect monoamine function in the brains of humans (Stanley *et al.*, 1985), they are an indirect measure of 5-HT function.

ILL AN and BN patients have abnormal levels of prolactin and other hormones in response to 5-HT specific challenges in most studies (Goodwin *et al.*, 1989; Brewerton *et al.*, 1990; Goldbloom *et al.*, 1990; Hadigan *et al.*, 1995; Jimerson *et al.*, 1997; Levitan *et al.*, 1997). After various degrees of recovery, hormonal responses tend to normalize in AN and BN, but some abnormal hormonal responses may persist (Wolfe *et al.*, 1994, 2000; Hadigan *et al.*, 1995; O'Dwyer *et al.*, 1996; Kaye *et al.*, 1998; Ward *et al.*, 1998). While hormones have been used as a reflection of CNS 5-HT, hormones are altered by malnutrition (Ishizuka *et al.*, 1983; Anderson *et al.*, 1990; O'Keane *et al.*, 1991) or may be relatively independent of brain 5-HT activity (McCann *et al.*, 1996).

Clinically, women with AN and BN appear to have opposing relationships between feeding and behavior. BN women are dysphoric when starved, whereas binge behavior appears temporarily to reduce dysphoric mood (Kaye *et al.*, 1986). In contrast, AN women describe feeling better when they starve. There is some evidence that these subgroups show different responses to 5-HT challenges. Studies that have examined the behavioral response to 5-HT challenges have found that depletion of tryptophan (TRP), the precursor of 5-HT (Fernstrom and Wurtman, 1971a, 1972) or serotonergic agents, such as mCPP, reduced dysphoric mood in ILL and REC AN subjects (O'Dwyer *et al.*, 1996; Gendall *et al.*, 1998; Ward *et al.*, 1998; Frank *et al.*, 2001; Kaye *et al.*, 2003). In contrast, in ILL and REC BN women, TRP depletion or mCPP is associated with increased caloric intake and dysphoric mood (Weltzin *et al.*, 1995; Kaye *et al.*, 1998, 2000; Smith *et al.*, 1999). In addition, BN individuals show an abnormal response to other measures, such as platelet binding of the selective serotonin reuptake inhibitor (SSRI) paroxetine (Steiger *et al.*, 2005a), which has

also been found to be altered in non-affected first-degree relatives (Steiger *et al.*, 2006).

#### *Diet and brain 5-HT neurotransmission*

Tryptophan (TRP), an essential amino acid only available in the diet, is the precursor of 5-HT. Meal consumption, depending on the proportion of carbohydrate and protein, can enhance brain 5-HT release (Fernstrom and Wurtman, 1971b, 1972); thereby affecting appetite regulation. In brief, carbohydrate consumption causes an insulin-mediated fall in plasma levels of the large neutral amino acids (LNAA, tyrosine, phenylalanine, valine, leucine, isoleucine) which compete with TRP for uptake into the brain. This elevates the plasma TRP/large neutral amino acid ratio (TRP/LNAA), and thus brain TRP, which rapidly accelerates brain 5-HT synthesis and release. Dietary proteins tend to block these effects by contributing large amounts of LNAA to the bloodstream. Considerable evidence in animals and healthy humans (Fernstrom and Wurtman, 1971b, 1972; Biggio *et al.*, 1974; Messing *et al.*, 1976; Gibbons *et al.*, 1979; Young and Gauthier, 1981; Anderson *et al.*, 1990) shows that a restricted diet significantly lowers plasma TRP, resulting in a decreased plasma ratio of TRP to neutral amino acids and, in turn, a reduction in the availability of TRP to the brain. Thus, restricted diet (and experimentally reduced TRP) decreases brain 5-HT synthesis, down-regulates the density of 5-HT transporters (Huether *et al.*, 1997), and produces a compensatory supersensitivity of post-synaptic receptors in response to reduced 5-HT turnover (Goodwin *et al.*, 1987a, 1987b). Limited data show that malnourished and emaciated AN women have a reduction of plasma TRP availability (Schweiger *et al.*, 1986). In addition, these alterations in post-meal amino acid metabolism are only partly reversed by nutritional rehabilitation (Schweiger *et al.*, 1986). It has been speculated (Vitousek and Manke, 1994; Strober, 1995) that dietary restraint may reduce anxiety in people with AN. In fact, we found that the anxiolytic effects of dieting in AN were related to a reduction in 5-HT neurotransmission (Kaye *et al.*, 2003). Furthermore, administration of meta-chlorophenylpiperazine (mCPP), a relatively selective serotonergic agent (Hoyer *et al.*, 1989; Kahn and Wetzler, 1991; Graeff *et al.*, 1996; Thomas *et al.*, 1996; Willins and Meltzer, 1997) was associated with a significant reduction in dysphoric mood states in one study (Frank *et al.*, 2001) but not in another (Hadigan *et al.*, 1995).

#### *Serotonin medication*

While BN individuals show a response to higher doses of fluoxetine, an SSRI (Fluoxetine Bulimia Nervosa Collaborative Study Group, 1992), the efficacy of such

medication has been questioned since relatively few individuals abstain from binge and purge behaviors, and relapse during treatment is common (Walsh and Devlin, 1995). Despite the abundance of data implicating 5-HT dysregulation in AN, it remains controversial whether SSRIs are effective in restricting-type AN (RAN) individuals (Kaye *et al.*, 2001; Walsh *et al.*, 2006). Our clinical experience (Kaye *et al.*, 1991b) suggests that RAN respond better to fluoxetine than do binge eating–purging type AN (BAN) individual, and that some BN individuals can be relatively insensitive to high doses of SSRIs. For severely emaciated patients, hospitalization for supportive medical care and weight restoration may be useful or necessary. Still, relapse is common after discharge.

### Brain imaging

The past decade has seen the introduction of tools, such as brain imaging, which hold the promise of characterizing complex neurocircuits and their relationship to behavior in living humans. In fact, these tools have rapidly advanced knowledge to the point where we can begin to make educated guesses about the pathophysiology of AN and BN and start to develop testable hypotheses about mechanisms.

Brain-imaging studies in AN and BN can be divided into several categories. First, there is a substantial literature, using computerized tomography (CT) and, more recently, magnetic resonance imaging (MRI), that has sought to determine whether there are brain structural alterations in individuals with ED. Second, there are imaging studies, such as positron emission tomography (PET) and single photon emission computed tomography (SPECT), that employ a radioligand. These studies, which may use fluorodeoxyglucose (FDG) to study glucose metabolism, or a ligand that is specific for a serotonin receptor, provide information that is specific for the system being studied, such as the 5-HT<sub>2A</sub> receptor. Third, more recent studies have used fMRI or other technologies to assess blood-flow responses to some stimuli, such as pictures of food. Overall, imaging studies have been relatively consistent, in that many studies show differences in ILL and REC ED individuals in frontal, cingulate, temporal and/or parietal regions compared to control subjects (CW). However, it should be noted that these studies have not consistently identified regions, pathways or behavioral correlates. Sample sizes have been small, and imaging technologies and methods vary widely. Moreover, investigations have tended to assess relatively large regions of the brain that vary widely between studies. Published studies to date indicate gross alterations of brain function. Because brain pathways are highly complex, the neuroanatomy of AN and BN has only begun to be characterized.

### Imaging studies of 5-HT function

The development of selective tracers for the 5-HT system has made *in vivo* study of 5-HT receptor function possible using PET brain imaging. In turn, this offers the possibility of better understanding of 5-HT neurotransmitter activity and dynamic relationships to behavior.

**5-HT<sub>1A</sub> receptor** Our group used PET imaging with the radioligand [<sup>11</sup>C]WAY100635 to assess the binding potential (BP) of the 5-HT<sub>1A</sub> receptor. The 5-HT<sub>1A</sub> autoreceptor is located presynaptically on serotonergic somatodendritic cells in the raphe nucleus, where it functions to decrease 5-HT neurotransmission (Staley *et al.*, 1998). High densities of postsynaptic 5-HT<sub>1A</sub> exist in the hippocampus, septum, amygdale, and entorhinal and frontal cortex, where they serve to mediate the effects of released 5-HT. Although the molecular organization for the receptor transduction seems to be identical in all of the areas where 5-HT<sub>1A</sub> receptors are expressed, some differences in both functional and regulatory properties have been reported from area to area (Lanfume and Hamon, 2000). Studies in animals and humans implicate the 5-HT<sub>1A</sub> receptor in anxiety (Cervo *et al.*, 2000; File *et al.*, 2000; Olivier *et al.*, 2001) and depression and/or suicide (Matsubara *et al.*, 1991; Arango *et al.*, 1995; Mann, 1999).

Bailer and colleagues (Bailer *et al.*, 2007a) reported that ILL AN individuals had a 50–70 percent increase in [<sup>11</sup>C]WAY100635 BP in subgenual, mesial temporal, orbital frontal and raphe brain regions, as well as prefrontal, lateral temporal, anterior cingulate and parietal regions. Similarly, REC BAN and BN subjects (Bailer *et al.*, 2005; Kaye, unpublished data; Figure 1) had a significant 20–40 percent increase in [<sup>11</sup>C]WAY100635 BP in these same regions compared to CW (Bailer *et al.*, 2005). In contrast, REC RAN women showed no difference in [<sup>11</sup>C]WAY100635 BP compared to controls (Bailer *et al.*, 2005). Increased 5-HT<sub>1A</sub> postsynaptic activity has also been reported in ILL BN subjects (Tiisonen *et al.*, 2004).

The role of the 5-HT<sub>1A</sub> receptor in behavior is not certain. 5-HT<sub>1A</sub> receptor activity has been reported to play a role in anxiety (File *et al.*, 2000). For example, some, but not all, studies show that 5-HT<sub>1A</sub> knockout mice have increased anxiety (Groenink *et al.*, 2003). REC RAN subjects showed positive relationships between harm avoidance, a trait characterized by anticipatory worry and fear of uncertainty, and postsynaptic [<sup>11</sup>C]WAY100635 BP in subgenual cingulate, mesial temporal, lateral temporal, medial orbital frontal and parietal cortex. It is not clear why this animal model and human phenomena appear to have opposite effects.

As noted above, EDs are frequently co-morbid with depression and anxiety disorders. Reduced [<sup>11</sup>C]WAY100635 BP has been found in ILL (Drevets *et al.*, 1999; Sargent

**Figure 1** Results of PET/[<sup>11</sup>C]WAY100635 BP (5-HT<sub>1A</sub> receptor) where individuals recovered from eating disorders (REC ED) are shown as percent of control subject (CW) values (mean CW values set at 100%). \**P* < 0.05 REC ED vs. CW.

*et al.*, 2000) and REC (Bhagwagar *et al.*, 2004) depressed subjects, as well as in a primate model for depression (Shively *et al.*, 2006). Parsey and colleagues found no difference in carbonyl-[<sup>11</sup>C]WAY100635 BP in major depressive disorder, although a subgroup of never medicated subjects had elevated carbonyl-[<sup>11</sup>C]WAY100635 BP (Parsey *et al.*, 2005). Recent studies have found reduced [<sup>11</sup>C]WAY100635 BP in social phobia (Lanzenberger *et al.*, 2007) and panic disorder (Neumeister *et al.*, 2004). These findings suggest that ED, mood and depression share disturbances of common systems but are etiologically different.

There is an extensive literature associating the serotonergic systems and fundamental aspects of behavioral inhibition (Soubrie, 1986; Geyer, 1996). Reduced CSF 5-HIAA levels are associated with increased impulsivity and aggression in humans and non-human primates, whereas increased CSF 5-HIAA levels are related to behavioral inhibition (Fairbanks *et al.*, 2001; Westergaard *et al.*, 2003). Brainstem 5-HT<sub>1A</sub> receptors inhibit stress-induced sympathetic activity and inhibit fight-or-flight behavioral responses, supporting a role for this receptor in behavioral inhibition and self-control (Johnson *et al.*, 2004). Furthermore, recent animal studies also support modulation of impulse control via 5-HT<sub>1A</sub> receptors through effects on catecholamine systems (Winstanley *et al.*, 2005). Other studies have shown that blunted 5-HT<sub>1A</sub> receptor number or function is associated with increased aggression (Coccaro *et al.*, 1990; Cleare and Bond, 2000). A recent study (Fischer *et al.*, 2007) found a significant inverse relationship between dorsal raphe 5-HT<sub>1A</sub> autoreceptor BP and bilateral amygdala reactivity. 5-HT<sub>1A</sub> receptor function could contribute to behavioral inhibition in BN, although there is no direct evidence for this conjecture. Still other studies show that various measures of 5-HT activity are related to measures of

affective instability and impulsivity in ill BN subjects (Steiger *et al.*, 2001a, 2001b, 2001c).

**5-HT<sub>2A</sub> receptor** Our group used PET imaging with the radioligand [<sup>18</sup>F]altanserin to assess BP of 5-HT<sub>2A</sub> receptors (Figure 2). Postsynaptic 5-HT<sub>2A</sub> receptors are present in high densities in the cerebral cortex and other brain regions of rodents and humans (Saudou and Hen, 1994; Burnet *et al.*, 1997). The 5-HT<sub>2A</sub> receptor is of interest in ED because it has been implicated in the modulation of feeding and mood, as well as SSRI response (Simansky, 1996; Stockmeier, 1997; Bonhomme and Esposito, 1998; De Vry and Schreiber, 2000; Bailer *et al.*, 2004).

ILL AN subjects had normal [<sup>18</sup>F]altanserin BP values (Bailer *et al.*, 2007a). In comparison, REC RAN individuals (Frank *et al.*, 2002) had reduced [<sup>18</sup>F]altanserin BP in mesial temporal and parietal cortical areas, as well as in subgenual and pregenual cingulate cortex. Similarly, REC BAN (Bailer *et al.*, 2004) women had reduced [<sup>18</sup>F]altanserin BP relative to controls in the left subgenual cingulate, left parietal, and right occipital cortex. Moreover, REC BN women only had reduced [<sup>18</sup>F]altanserin BP relative to controls in the orbitofrontal region. Audenaert *et al.* (2003) used SPECT and 123I-5-I-R91159 and found that ILL AN subjects had reduced binding of postsynaptic 5-HT<sub>2A</sub> receptors in the left frontal, bilateral parietal and occipital cortex, with bulimic type BAN having reduced 5-HT<sub>2A</sub> binding in the parietal cortex in comparison to RANs (Goethals *et al.*, 2007).

**Brain regions/pathways enervated by 5HT<sub>1A/2A</sub> receptors**  
In REC subjects, altered 5-HT<sub>1A</sub> and 5-HT<sub>2A</sub> receptor BP shows persistent alterations in frontal, subgenual cingulate

**Figure 2** Results of PET/[18F]altanserin binding potential (5-HT<sub>2A</sub> receptor) where individuals recovered from eating disorders (REC ED) are shown as percent of control subject (CW) values (mean CW values set at 100%). \* $P < 0.05$  REC ED vs. CW.

and mesial temporal regions that are part of the ventral limbic system. The subcaudal cingulate regions play a role in emotion ('affect component') and have extensive connections with the amygdala, periaqueductal gray, frontal lobes and ventral striatum. They are involved in conditioned emotional learning, vocalizations associated with expressing internal states, and assigning emotional valence to internal and external stimuli (Freedman *et al.*, 2000). Mesial temporal regions include the amygdala and related regions that play a pivotal role in anxiety and fear (Charney and Deutch, 1996) as well in the modulation and integration of cognition and mood. The amygdala may enable the individual to initiate adaptive behaviors to threat, based upon the nature of the threat and prior experience.

Several lines of evidence show that 5-HT<sub>1A</sub> and 5-HT<sub>2A</sub> receptors interact in the brain. In rats, 5-HT<sub>1A</sub> and 5-HT<sub>2A</sub> receptors interact robustly to regulate the inhibition of exploration of novel environments produced by either 5-HT<sub>1A</sub> or 5-HT<sub>2A</sub> receptor agonists (Krebs-Thomson and Geyer, 1998). 5-HT<sub>2A</sub> and 5-HT<sub>1A</sub> receptors are highly co-localized in rodent frontal cortex (Amargos-Bosch *et al.*, 2004). Postsynaptic 5-HT<sub>1A</sub> and 5-HT<sub>2A</sub> receptors mediate, respectively, the direct hyperpolarizing and depolarizing actions of 5-HT on prefrontal neurons (Santana *et al.*, 2004), which in turn project to numerous cortical and subcortical areas. Thus, a balance between postsynaptic 5-HT<sub>1A</sub> and 5-HT<sub>2A</sub> receptor activity on neurons may modulate the descending excitatory input into limbic and motor structures. These data raise speculation that postsynaptic 5-HT<sub>1A</sub> and 5-HT<sub>2A</sub> receptors fine-tune cortical systems that modulate behavioral inhibition and self-control. Mixed 5-HT<sub>2A/1A</sub> agonists, such as psilocybin, seem to disrupt the 5-HT<sub>1A/2A</sub> balance (Vollenweider *et al.*, 1999) by driving 5-HT<sub>2A</sub> activity, thus resulting in excessive neuronal output that contributes to extremes of

disinhibition, disorganization, and loss of self-control. In our studies, REC ED subjects had a relative increase in 5-HT<sub>1A</sub> receptor activity compared to 5-HT<sub>2A</sub> receptor binding. While speculative, this possible imbalance could contribute to behavioral inhibition and over-control commonly seen in ED. As discussed below, we found considerable correlations between binding of these two receptors and harm avoidance. Taken together, these findings raise the possibility that mesial temporal (amygdala)–cingulate 5HT<sub>1A/2A</sub> imbalance may also be a trait shared by AN subgroups related to behavioral inhibition, anticipatory anxiety, or integration of cognition and mood.

#### 5-HT transporter (5-HTT)

Studies with SPECT and [123I] beta-CIT showed that ILL BN subjects had a 17 percent reduced 5-HTT availability in the hypothalamus and thalamus (Tauscher *et al.*, 2001). Our group (Bailer *et al.*, 2007b) used PET imaging with [<sup>11</sup>C]McN5652 to determine if alterations of 5-HTT persist after recovery from AN and BN. We compared 11 subjects recovered (>1 year normal weight, regular menstrual cycles, no bingeing or purging) from restricting type AN (REC RAN), 7 REC from bulimia-type AN (REC BAN), and 10 healthy CW. After correcting for multiple comparisons, we found that the REC RAN had significantly increased [<sup>11</sup>C]McN5652 BP compared to REC BAN for the dorsal raphe and antero-ventral striatum. A SPECT study compared 5-HTT availability in the midbrain and thalamus in 13 female twins with BN (9 with purging and 4 with non-purging) versus 25 CW, using a different radioligand for 5-HTT, [123I]ADAM (Koskela *et al.*, 2007). They found that purging bulimics had increased midbrain [123I]ADAM binding compared to CW, supporting a serotonin-based distinction between those with purging and non-purging behaviors, across both studies. Differences in sample selection, imaging

resolution of the methods, the regional binding of the radioligands and the data analysis approaches likely contributed to whether 5-HTT binding was relatively elevated or diminished in those with purging behaviors. It remains controversial whether SSRIs are effective in RAN individuals. Our clinical experience and data (Kaye *et al.*, 1991b, 2001; Walsh *et al.*, 2006) suggest that individuals with RAN respond better to fluoxetine than do those with BAN. While highly speculative, our findings raise the provocative possibility that decreased 5-HTT function may be related to poor response to SSRI medication, whereas individuals with increased 5-HTT activity may respond to higher SSRI doses. In general, the REC RAN individuals had elevated 5-HTT binding, suggesting that they have relatively greater 5-HT uptake, and reduced extracellular 5-HT, compared to REC BAN. In support of this possibility, the REC BAN individuals tend to have higher binding of 5-HT<sub>1A</sub> postsynaptic receptors and autoreceptors (Bailer *et al.*, 2005), which may be a compensatory means of downregulating raphe activity (Cooper, 1996; Hajos *et al.*, 2003). Moreover, reduced 5-HTT activity, resulting from functional polymorphisms (Steiger *et al.*, 2005b), has been associated with affect dysregulation, which tends to be more common in the bulimic subgroups. Traits such as sensation-seeking and insecure attachment are elevated in bulimic syndromes carrying low function alleles of the 5-HTT promoter polymorphism, who report prior physical or sexual maltreatment (Steiger *et al.*, 2007). Furthermore, in people with impulsive aggression, reduced 5-HTT binding was found in the anterior cingulate cortex – a region involved in affect regulation (Frankle *et al.*, 2005).

#### *5-HT and harm avoidance*

The PET imaging studies in ILL and REC AN and BN subjects described above have found significant correlations between harm avoidance and binding for the 5-HT<sub>1A</sub> and 5-HT<sub>2A</sub> receptors in mesial temporal and other limbic regions. Bailer and colleagues have found that REC AN–BN subjects showed a positive relationship between [<sup>18</sup>F]altanserin BP in the left subgenual cingulate and mesial temporal cortex and harm avoidance (Bailer *et al.*, 2004). For ILL AN subjects, [<sup>18</sup>F]altanserin BP was positively related to harm avoidance in the supragenual cingulate, frontal and parietal regions. 5-HT<sub>2A</sub> receptor binding and harm avoidance were shown to be negatively correlated in the frontal cortex in healthy subjects (Moresco *et al.*, 2002), and in the prefrontal cortex in patients who attempted suicide (van Heeringen *et al.*, 2003). Furthermore, genetic studies have shown that the low 5-HTT activity polymorphism (125 women with BN and 94 CW (Monteleone *et al.*, 2006)) as well as the A218C polymorphism of the biosynthetic tryptophan

hydroxylase-1 gene (91 women with BN and 89 CW (Monteleone *et al.*, 2007)) predispose BN individuals to increased harm avoidance.

Clinical and epidemiological studies have consistently shown that one or more anxiety disorders occur in the majority of people with AN or BN (Kendler *et al.*, 1995; Walters and Kendler, 1995; Godart *et al.*, 2002; Kaye *et al.*, 2004a). Silberg and Bulik, using twins, found a unique genetic effect that influences liability to early anxiety and eating disorder symptoms (Silberg and Bulik, 2005). When a lifetime anxiety disorder is present, the anxiety most commonly occurs first in childhood, preceding the onset of AN or BN (Deep *et al.*, 1995; Bulik *et al.*, 1997a; Godart *et al.*, 2000). Anxiety and harm avoidance remain elevated after recovery from AN, AN–BN and BN (Wagner *et al.*, 2006), even if individuals had never had a lifetime anxiety disorder diagnosis (Kaye *et al.*, 2004a). Finally, anxiety (Spielberger *et al.*, 1970) and harm avoidance from the Cloninger Temperament and Character Inventory (TCI) (Cloninger *et al.*, 1994) have been robust signals in our genetic studies (Bacanu *et al.*, 2005). In summary, the premorbid onset and the persistence of anxiety and harm avoidance symptoms after recovery suggest that these are traits that contribute to the pathogenesis of AN and BN. The PET imaging data suggest that such behaviors are related to disturbances of 5-HT neurotransmitter function in limbic and executive pathways.

#### **Implications**

Phillips and colleagues (2003) have described a ventral limbic system, containing the amygdala, insula, ventral striatum and ventral regions of the anterior cingulate gyrus and prefrontal cortex, which identifies the emotional significance of a stimulus and the production of an affective state in response to that stimulus. In addition, these regions are important for automatic regulation and mediation of autonomic responses to emotional stimuli and contexts accompanying the production of affective states.

The findings described above offer evidence that individuals with ED have 5-HT dysregulation within brain regions that constitute limbic circuits. In general, such alterations tend to be present in the ill state and persist after recovery. Patterns of 5-HT receptor binding vary by subtype in the REC subjects, raising the possibility that each ED subtype has a unique pathophysiology (Table 3). Similar patterns of binding (elevated 5-HT<sub>1A</sub> and reduced 5-HT<sub>2A</sub>) have also been found in other temporal, cingulate and parietal regions, suggesting a widespread distribution involving more than just limbic function.

**Table 3** PET findings with serotonin radioligands in ED

	AN	AN-BN	BN
ROI	Medial orbital frontal, subgenual cingulate, mesial temporal		
5-HT <sub>1A</sub> BP	—	↑	↑
5-HT <sub>2A</sub> BP	↓	↓	—
ROI	Anterio-ventral striatum		
5-HTT BP	↑	↓	—

Abbreviations: AN, anorexia nervosa; BN, bulimia nervosa; BP, binding potential; ROI, region of interest.

Drawing inferences about behavior from these 5-HT findings is speculative. Moreover, no receptor works in isolation in the brain. Monoamine enervation of limbic pathways is complex, and involves many pathways, receptors, enzymes, intracellular transcription messengers, other neurotransmitters and molecules. It can be hypothesized that these receptor findings might reflect the ‘health’ of the 5-HT function within limbic circuits, but not necessarily be the specific cause of these disorders. The genetic literature suggests that behavioral disorders are complex and consist of multiple factors, each of small effect. Finally, altered 5-HT receptor binding is often found in depression and anxiety, although patterns of binding tend to be different. Disturbances of affect and impulse regulation may involve similar pathways, but with very different patterns of molecular disturbances.

Conclusion

We hypothesize that a trait-related disturbance of 5-HT neuronal modulation predates the onset of AN and contributes to premorbid symptoms of anxiety and inhibition. This dysphoric temperament may involve an inherent dysregulation of emotional and reward pathways (Kelley, 2004), which also mediate the hedonic aspects of feeding, thus making these individuals vulnerable to disturbed appetitive behaviors. This 5-HT disturbance contributes to a vulnerability for restricted eating and dysphoric mood states such as increased harm avoidance. Most importantly, we think that restricting food intake is powerfully reinforcing because it provides a temporary respite from dysphoric mood. Several factors may act on these vulnerabilities to cause AN to start in adolescence. First, puberty-related female gonadal steroids or age-related

changes may exacerbate 5-HT dysregulation. Second, stress and/or cultural and societal pressures may contribute by increasing anxious and obsessional temperament. We hypothesize that people with AN may discover that reduced dietary intake, by reducing plasma TRP availability (Schweiger *et al.*, 1986), is a means by which they can crudely modulate brain 5-HT functional activity and anxious mood (Kaye *et al.*, 2003). People with AN enter a vicious cycle, which accounts for the chronicity of this disorder, because caloric restriction results in a brief respite from dysphoric mood. However, malnutrition and weight loss, in turn, produce alterations in many neuropeptides and monoamine function, perhaps in the service of conserving energy, but which also exaggerate dysphoric mood. Thus, those with AN pursue starvation in an attempt to avoid the dysphoric consequences of eating. SSRI administration does not appear to be effective in counteracting 5-HT disturbances in patients ill with AN, perhaps because of the extreme changes induced by malnutrition in the 5-HT<sub>1A</sub>-receptor and extracellular 5-HT concentrations.

# Genetic, Epigenetic and Environmental Factors in Serotonin Associated Disease Condition

Eva Friedel and Andreas Heinz\*

*Department of Psychiatry and Psychotherapy, Charité - University Medicine Berlin, Germany*

**Abstract:** Genetic, epigenetic and environmental factors have been shown to influence serotonergic neurotransmission implicated in psychiatric and neurologic disorders. Due to the prominent effects of serotonin reuptake inhibition on negative mood states, a series of studies examined central serotonin transporter (5-HTT) availability and turnover in patients suffering from major depression, anxiety, obsessive-compulsive disorder and alcohol dependence. Human studies and animal experiments in rodents and non-human primates identified effects of genetic, epigenetic and environmental factors that modulate 5-HTT mRNA transcription and *in vivo* availability. In this chapter we review the literature and discuss studies in non-human primates that underwent social stress and displayed a reduction of the serotonin turnover rate among carriers of one or two short alleles of a functional polymorphism of the 5-HTT regulatory region. Further studies in these primates suggested specific effects of stress hormone responses on serotonin transporter availability depending on 5-HTT genotype and gender. In humans suffering from negative mood states such as depression or alcoholism, reduced availability of brainstem and thalamic serotonin transporters was associated with anxiety and may reflect stress exposure mediated by epigenetic interactions between stress hormone levels, gender and 5-HTT genotype that bias central processing of emotionally salient information.

**Keywords:** serotonin transporters, SLC6A4, anxiety, impulsivity, negative mood states, reversal learning.

## Introduction

Serotonergic neurons are located in the brainstem raphe nuclei, from where they project to a multitude of brain areas and stimulate a wide range of serotonin receptor subtypes (Baumgarten and Grozdanovic, 1997). Serotonergic dysfunction was implicated in a variety of psychiatric disorders, and may primarily contribute to negative affect such as anxiety and depression (Cloninger, 1987; Owens and Nemeroff, 1994; Grove *et al.*, 1997). Uptake of intrasynaptic serotonin is regulated by the function and availability of serotonin transporters (5-HTT). A two-fold difference in serotonin reuptake rates was associated with a functional polymorphism in the regulatory region of the 5-HTT gene, and may contribute to the risk of developing negative mood states (Lesch *et al.*, 1996; Caspi *et al.*, 2003). Besides negative mood states such as anxiety and depression (Praag, 1977; Traskman-Bendz *et al.*, 1984; Artigas, 1995; Mann *et al.*, 1996; Barr *et al.*, 2003), serotonergic

dysfunction may also contribute to the pathogenesis and maintenance of impulsive behavior, aggressiveness and excessive alcohol intake (LeMarquand *et al.*, 1994; FilsAime *et al.*, 1996). Serotonergic neurotransmission modulates the acute response to alcohol; a low response to the acute effects of alcohol intake was found both in humans with a 5-HTT genotype that is associated with high *in vivo* 5-HTT availability, and in non-human primates displaying a comparable increase in brainstem 5-HTT availability in association with a stress-induced decrease in serotonin turnover rates (Doudet *et al.*, 1995; Schuckit and Smith, 1996; Heinz *et al.*, 1998a; Schuckit *et al.*, 1999; Barr *et al.*, 2003; Hu *et al.*, 2005). These observations appear to be of clinical relevance, because a low level of response to acute alcohol intake is more common in relatively alcohol-naïve children of alcoholics and is predictive of subsequent alcohol abuse and dependence (Rodriguez *et al.*, 1993; Schuckit *et al.*, 1999; Schuckit and Smith, 1996; Volavka *et al.*, 1996). In this chapter, we will discuss behavioral correlates of central serotonergic neurotransmission and focus on negative mood states and a low response to alcohol as behaviorally relevant correlates of serotonin function.

### Genetic, epigenetic and environmental effects that modulate serotonergic neurotransmission

Genetic, epigenetic and environmental factors contribute to central serotonin turnover as assessed by the serotonin metabolite 5-hydroxyindoleacetic acid (5-HIAA) in the cerebrospinal fluid (CSF) (Oxenstierna *et al.*, 1986; Higley *et al.*, 1991, 1993; Clarke *et al.*, 1996). Serotonin turnover rates can be measured *in vivo* in non-human primates, and heritability estimates of serotonin turnover accounted for 42 percent of the variance (Kaplan, 2000) – a number that is rather close to heritability estimates in human twin studies, which accounted for about 35 percent of the variance in CSF 5-HIAA concentrations; therefore, epigenetic and environmental factors appear to play a predominant role in the regulation of central serotonin turnover (Beck *et al.*, 1984; Oxenstierna *et al.*, 1986). Environmental factors are of special interest if they have long-lasting effects on serotonergic neurotransmission, and such lasting effects were observed following developmentally early social separation stress (Higley *et al.*, 1991; Jones *et al.*, 1992; Clarke *et al.*, 1996).

Intrasyaptic serotonin concentrations are modulated by the availability and functional capacity of serotonin transporters (5-HTT), which regulate reuptake of extracellular serotonin. A variable number of tandem repeat (VNTR) polymorphic sites in the regulatory unit of the serotonin transporter gene (SLC6A4) has been shown to influence serotonin transporter expression: homozygous carriers of a long allele (*ll*-genotype) express about twice as many serotonin transporters as carriers of one or two short alleles (*s*-carriers) (Lesch *et al.*, 1996; Little *et al.*, 1998; Heinz *et al.*, 2000). A subsequently discovered A > G exchange in the 5-HTT regulatory region was associated with differential transcriptional activation of 5-HTT mRNA in lymphoblastoid cell lines (Hu *et al.*, 2006), and *in vivo* imaging studies suggested that carriers of two long (*ll*) alleles of the 5-HTT regulator region express elevated serotonin transporter availability only if they do not carry the A > G exchange (*l<sub>A</sub>l<sub>A</sub>* homozygotes) (Praschak-Rieder *et al.*, 2007; Reimold *et al.*, 2007). One previous study that reported increased radioligand binding in *ll* homozygotes was reanalyzed, and revealed that all *ll* indeed carried the *l<sub>A</sub>l<sub>A</sub>* genotype.

Stress exposure is one environmental factor that was examined in the context of gene–environment interactions and their effect on central serotonin function. A brain-imaging study in non-human primates used single photon emission tomography (SPECT) and a radioligand that binds with high affinity to central serotonin transporters to assess *in vivo* serotonin transporter availability and its interaction with serotonin turnover rates. The adult rhesus macaques examined in this study had experienced social

isolation stress during their early development (Heinz *et al.*, 1998a). In previous studies, concentrations of the serotonin metabolite 5-HIAA in the CSF were decreased in primates that had been separated from their mothers after birth and peer-raised as compared with mother-reared animals, and CSF 5-HIAA levels decreased further when the primates were completely isolated from their peers (Clarke *et al.*, 1996; Higley *et al.*, 1996). Such reductions in CSF 5-HIAA concentrations were trait-like, and persisted during adulthood (Higley *et al.*, 1996; Heinz *et al.*, 1998a). The rhesus macaques displayed increased anxiety-like behaviors during early social isolation stress exposure (Higley *et al.*, 1991); when the male monkeys reached adulthood, they displayed an increased impulsive aggressiveness (Higley *et al.*, 1996), which was correlated with low CSF 5-HIAA concentrations and an increased availability of serotonin transporters in the brainstem (raphe) area with low CSF 5-HIAA availability (Heinz *et al.*, 1998a). Low CSF 5-HIAA concentrations and a high availability of brainstem 5-HTT were also associated with an increased frequency of self-initiated aggressive acts, and reduced time spent in social contacts (Heinz *et al.*, 1998a). Gender differences may play a role, because it was observed that in female rhesus monkeys low CSF 5-HIAA levels were correlated with low-intensity, restrained aggression, a behavior pattern that is found in matrilineal defense of social status (Westergaard *et al.*, 2003).

The effects of early social isolation stress on serotonin turnover rates (measured as CSF 5-HIAA concentrations) interacted with genetic variance in the structure of the regulatory region of the 5-HTT gene: only carriers of one or two short (*s*) alleles of the 5-HTT regulatory region displayed a reduction in serotonin turnover rates following social isolation, while this was not the case in homozygote carriers of two long (*l*) alleles (Bennett *et al.*, 2002). When the rhesus monkeys were further isolated from their peers – i.e., experienced complete social isolation during the first 6 months of life – carriers of one or two *s* alleles of the 5-HTT regulatory region displayed increased levels of adrenocorticotropin hormone (ACTH) and cortisol compared to *ll* homozygotes (Barr *et al.*, 2004). Animal experiments suggest that stress-associated activation of the hypothalamic–pituitary–adrenal (HPA) axis may further interfere with serotonergic neurotransmission via down-regulation of serotonin transporters (Slotkin *et al.*, 1997). Also in human alcohol-dependent patients and healthy control subjects, plasma cortisol concentrations were negatively correlated with the availability of brainstem 5-HTT (Heinz *et al.*, 2002; Figure 1).

In non-human primate imaging studies, a high availability of raphe serotonin transporters was associated with low CSF 5-HIAA concentrations – a finding that may be due to a real increase in serotonin transporter

**Figure 1** In male healthy control subjects (squares) and alcohol-dependent patients during early abstinence, high cortisol plasma concentrations (as observed during detoxification) are associated with low binding of the radioligand iodine-123- $\beta$ -CIT to brainstem (raphe) serotonin transporters. Modified from Heinz *et al.*, 2002, by permission from Georg Thieme Verlag KG.

density. Such an increase in functional reuptake capacity could cause a reduction in extracellular concentrations of monoamine neurotransmitters and their metabolites. A *post-mortem* study in non-human primates supported this hypothesis, and observed a negative correlation between striatal dopamine transporter density and individual concentrations of the dopamine metabolite homovanillic acid (HVA) (Mash *et al.*, 1996). This observation was further confirmed in a combined microdialysis and SPECT study, which showed that the availability of monoamine transporters negatively correlated with extracellular neurotransmitter concentrations (Heinz, 1999). Conversely, blockade or loss of serotonin or dopamine transporters induces a dramatic increase in extracellular neurotransmitter concentrations in, for example, knockout animal models (Kreiss and Lucki, 1995; Giros *et al.*, 1996). These observations support the hypothesis that extracellular monoamine concentrations are regulated by monoamine reuptake capacity. However, an alternative explanation is also possible: low extracellular 5-HIAA concentrations may be correlated with increased binding of the radiotracers to monoamine reuptake sites (transporters) because of decreased competition between endogenous serotonin and the applied radioligand (Jones *et al.*, 1998; Figure 2).

Indeed, when synaptic serotonin (5-HT) levels were restored after serotonin depletion in non-human primates, this was accompanied by a significant reduction in radioligand binding raphe 5-HTT (Heinz *et al.*, 2004). Independent of the underlying nature of the neurobiological process, *in vivo* and *in vitro* studies suggest inverse correlations between serotonin transporter availability and both extracellular neurotransmitter concentrations and serotonin metabolite levels in CSF (Heinz *et al.*, 1998a, 2002).

**Figure 2** Competition between endogenous extracellular serotonin levels and radioligands such as iodine-123- $\beta$ -CIT that bind to presynaptic (left) serotonin transporters (*Upper panel*): when extracellular serotonin concentrations are high, presynaptic serotonin transporters are occupied to a considerable degree by endogenous serotonin and radioligand binding is relatively low. (*Lower panel*): low extracellular serotonin concentrations occupy less serotonin reuptake sites and radioligand binding is relatively high.

Genetic factors, epigenetic programming and environmental factors have been implicated in the etiology of depression and anxiety. Nevertheless, it remains unclear what exactly causes the observed neurochemical changes that are considered crucial, like serotonin and catecholamine variations, elevated levels of CRH and nerve growth factor quantities. Previous stress exposure, especially when occurring early in life, has great impact on the reactivity to stressors. These stressor effects might reflect sensitization of neuronal functioning, phenotypic changes of processes that lead to neurochemical release or receptor sensitivity, or epigenetic processes that modify

the expression of specific genes associated with stressor reactivity (Anisman *et al.*, 2008). Experiences of stressful life events in early pregnancy or during postnatal development are able to induce epigenetic effects such as alterations in DNA methylation and transcription (Weaver *et al.*, 2007; Mueller and Bale, 2008; Oberlander *et al.*, 2008a, 2008b). Moreover, such stress exposure can lead to maladaptive stress responses and anhedonia later in life (Mueller and Bale, 2008). Long-term alterations in central corticotropin-releasing factor (CRF) and glucocorticoid receptor (GR) expression, as well as dysregulated hypothalamic–pituitary–adrenal (HPA) axis responsivity and altered serotonin transporter availability, are probable factors contributing to elevated stress sensitivity later in life (Oberlander *et al.*, 2008a).

Sex-specific differences in prenatal stress vulnerability were described in animal experiments (Mueller and Bale, 2008), with an increased vulnerability of male offspring to maternal stress in early gestation due to stress effects on placental function in male but not female placentas. In this study changes in CRF glucocorticoid receptor (GR) gene methylation were associated with altered gene expression, and provide evidence of epigenetic programming during early pregnancy. Human studies confirm that prenatal (Oberlander *et al.*, 2008b) and postnatal (Oberlander *et al.*, 2008a) stress exposure is associated with increased stress reactivity in early infancy via gene modulation. For example, methylation status of a CpG-rich region in the promoter and exon 1F of the human glucocorticoid receptor (GR) gene (NR3C1) in newborns is sensitive to prenatal maternal mood, and may offer a potential epigenetic process that links prenatal maternal mood and altered hypothalamic–pituitary–adrenal (HPA) axis stress reactivity during infancy (Oberlander *et al.*, 2008a).

Postnatal differences in nurturing behavior influence glucocorticoid receptor (GR) gene expression in the hippocampus of mice offspring (Weaver *et al.*, 2007): increased postnatal licking/grooming behavior enhanced the binding of nerve growth factor inducible protein A (NGFI-A) transcription factor to the exon 1(7) GR promoter within the hippocampus of the offspring. Knock-down experiments regarding NGFI-A in hippocampal primary cell culture showed that NGFI-A is required for serotonin-induced DNA demethylation and increased exon 1(7) GR promoter expression, which may contribute to protection from stress exposure. These findings suggest a protective mechanism that directly links the effect of maternal care on both gene expression and stress sensitivity. Conversely, NGFI-A binding to its response element is inhibited by DNA methylation. Human data (Oberlander *et al.*, 2008a) describe similar influences of maternal care (here, breastfeeding) on the developing HPA regulation system in 3-month-old infants.

In adults, stress experiences have been linked to the 5-HTT genotype (Caspi *et al.*, 2003), postulating a ‘risk’ genotype associated with the short allele of the 5-HTT gene, leading to increased levels of depression following stressful life events compared to carriers of the long allele. Recent studies offer a potential account of this mechanism. Philibert and coworkers described a CpG island in the 5′ region of the 5-HTT gene that contains an alternative exon 1 and possible promoter for 5-HTT. An increase of CpG methylation was associated with decreased transcription of 5-HTT mRNA (Philibert *et al.*, 2008). Women displayed increased levels of CpG methylation and, respectively, low levels of 5-HTT mRNA (Philibert *et al.*, 2008), implicating a sex-specific vulnerability for developing mood disorders, whereas male subjects showed higher 5-HTT mRNA expression. Carrying a short allele of the 5-HTT regulatory region was also associated with lower amounts of 5-HTT mRNA transcription, explaining up to 10 percent of the observed variance (Philibert *et al.*, 2008). Altogether, these findings suggest that prenatal and postnatal stress exposure can induce long-lasting alterations in stress hormone axis activation, and may impact on serotonergic neurotransmission. Early human imaging studies directly linked acute stress hormone elevations with reductions in serotonin transporter availability and with negative mood states (Heinz *et al.*, 2002), thus providing additional evidence for interactions between stress exposure and serotonin dysfunction.

### **Aggression and impulsivity as behavioral manifestations of central serotonergic dysfunction**

Impulsive and aggressive behavior may be a primary or secondary correlate of reduced central serotonin turnover. Gray (1982) hypothesized that serotonergic activation of the septo-hippocampal behavior inhibition system (BIS) is unpleasant and therefore experienced as punishment, which induces passive avoidance (Gray, 1982). Serotonergic dysfunction may thus interfere with the function of the behavior inhibition system, and this lack of behavioral control would then manifest as impulsiveness and uncontrolled aggressive behavior. However, further studies suggested that impulsive aggressiveness is not a specific correlate of central serotonergic dysfunction, which instead is primarily associated with negative mood states such as anxiety or depression (Owens and Nemeroff, 1994; Young *et al.*, 1994; Artigas, 1995; Knutson *et al.*, 1998). This hypothesis is supported by the primarily pleasant effects of methylenedioxymethamphetamine (MDMA, ‘ecstasy’), which have been associated with acute increases in serotonin release (Huether *et al.*, 1997). In a human study, medication with selective serotonin

reuptake inhibitors (SSRIs) has been associated with improvement of negative mood states due to an *increase* rather than a decrease in synaptic serotonin concentrations, and this observation is difficult to reconcile with the notion of serotonergic neurotransmission stimulating a punishment system (Limberger *et al.*, 1990; Artigas, 1995; Kreiss and Lucki, 1995; Muck-Seler *et al.*, 1996). Human CSF studies observed a significant association between the clinical remission of depressive symptoms and an *increase* in primarily low CSF 5-HIAA concentrations (Praag, 1977; Traskman-Bendz *et al.*, 1984). Serotonin depletion studies pointed in the same direction by showing that reduced serotonin content induced negative mood states in patients suffering from obsessive-compulsive disorder, and among patients with major depression who previously displayed an improvement of their depressive symptoms following SSRI medication (Delgado *et al.*, 1990; Barr *et al.*, 1994). Altogether, these studies suggest that an increase in synaptic serotonin concentrations induces a *reduction* in negative mood states such as anxiety and depressiveness, rather than representing the neurobiological correlate of punishment.

So how can the association between low serotonin turnover rates and impulsive aggression be explained? The correlation between reduced central serotonergic dysfunction and both impulsive aggression and negative mood states may derive from common ground: individuals who are overwhelmed by feelings of insecurity and threat may respond with impulsively aggressive behavior (Heinz *et al.*, 2001). This hypothesis is based on animal experiments and human studies. In rodents, increased serotonin turnover was associated with higher social competence in competitive games (Knutson *et al.*, 1996a), while serotonin depletion induced anxious and insecure behavior patterns (Knutson *et al.*, 1996b). A human study of Knutson *et al.* (1998) demonstrated that SSRI application primarily induced a reduction in negative mood among individuals engaging in a competitive game. Specifically, Knutson and coworkers (1998) observed that the reduction in aggressive behavior which occurred following SSRI application was statistically explained by the decrease in negative emotions. The reduction in aggressiveness may thus be due to a decrease in perceptions of threat and insecurity.

On the other hand, a high serotonin turnover rate may protect against the impact of threat-related environmental cues: serotonergic neurotransmission modulates thalamo-cortical circuits and may thus support a 'protective filter effect' that reduces the impact of sensory inputs (McCormick, 1992; Baumgarten and Grozdanovic, 1997). Indeed, genetic variation in serotonin transporter expression and function has been associated with limbic, particularly amygdala, responses to aversive environmental stimuli (Hariri *et al.*,

2002; Heinz *et al.*, 2005). Exacerbation of central serotonergic dysfunction during clinically relevant negative mood states may lead to over-activation of the amygdala by aversive environmental stimuli, a hypothesis that was supported by the observation of increased glucose turnover rates in the amygdala of patients suffering from major depression (Drevets, 2000).

Altogether, these observations suggest that serotonergic neurotransmission promotes feelings of security and tranquility (Raleigh *et al.*, 1988; Knutson, 1996b), while subjects suffering from a deficit in serotonergic neurotransmission may feel threatened, insecure and anxious (Higley *et al.*, 1991; Jones *et al.*, 1992; Clarke *et al.*, 1996). In this view, the manifestation of clinically relevant syndromes such as clinical depression or impulsive aggression after serotonin depletion are secondary consequences from general feelings of insecurity and tension that manifest as negative mood states (Knutson *et al.*, 1998; Heinz *et al.*, 2001). Whether behavioral responses are more tuned towards depression or aggression may depend upon the manifestation of other causal factors, such as learned behavior in social contexts, which is modulated by, for example, socially constructed roles of men and women (Kraemer and McKinney, 1979; Raleigh, 1991; Heinz *et al.*, 2001). *In vivo* interactions between serotonergic dysfunction, amygdala activation and specific negative mood states will have to be explored in future studies.

### Serotonergic neurotransmission and the response to acute alcohol intake

It has been suggested that early onset of alcoholism (i.e., before 25 years of age) is characterized by increased impulsiveness, aggressive behavior and serotonin dysfunction (FilsAime, 1996). The suggested association between dysfunction of central serotonergic neurotransmission, impulsive aggression and excessive alcohol intake has been explored in a series of animal experiments and human studies. In humans and non-human primates, individuals who show a low response to the acute effects of alcohol may fail to experience the negative consequences of excessive alcohol intake, and thus lack a 'warning signal' that limits the amount of alcohol consumed. Studies among adolescents and young adults confirmed that a low response to acute alcohol intake was indeed associated with excessive drinking during longer observation periods, and with an increased risk to develop alcohol dependence in prospective studies (Schuckit and Smith, 1996; Schuckit *et al.*, 1999; Hinckers *et al.*, 2006). Reduced serotonin turnover rates and a high availability of serotonin transporters appear to represent one factor

that contributes to a low alcohol response: following alcohol intake, reduced sedation and ataxia were observed in non-human primates with a genetic disposition to elevated serotonin transporter availability and function (i.e., carriers of two long alleles of the 5-HTT regulatory region compared with carriers of one or two short alleles) (Barr *et al.*, 2003). A decrease in serotonin turnover rates in association with elevated raphe serotonin transporter and a low response to alcohol can also result from environmental factors such as early social isolation stress, because it was observed in non-human primates separated from their mothers after birth compared with animals that were raised by their mothers (Heinz *et al.*, 1998a). Low serotonin turnover rates appear to contribute to a low alcohol response by reducing the sedative, GABAergic effects of acute alcohol intake. The sedative effects of ethanol are mediated by activation of GABA<sub>A</sub> receptors (Liljequist and Engel, 1982; Silveri and Spear, 2002) and by blockade of glutamatergic NMDA receptors, particularly after consumption of high doses of alcohol (Tsai *et al.*, 1995; Krystal *et al.*, 1998). Dysfunction of serotonergic neurotransmission in the prefrontal cortex modulates both GABAergic and glutamatergic neurotransmission via 5-HT<sub>1A</sub> and 5-HT<sub>4</sub> receptors (Krystal, 1999; Feng *et al.*, 2001; Cai *et al.*, 2002a, 2002b; Figure 3).

Therefore, low serotonin turnover rates may reduce the sedative effects of acute alcohol intake via modulation of prefrontal GABAergic and glutamatergic alcohol effects, and indeed Doudet and coworkers observed that low CSF 5-HIAA concentrations following social isolation stress

in non-human primates were associated with reduced effects of GABAergic stimulation on prefrontal glucose utilization rates (Doudet *et al.*, 1995). In further studies with non-human primates that suffered from social isolation during their early development, low CSF 5-HIAA levels and a high availability of serotonin transporters were associated with both a low acute response to alcohol and an increased alcohol intake in a 3-month observation period when they had access to alcohol in a free choice paradigm (Heinz *et al.*, 2003).

### Disposition to excessive alcohol intake: gene–environment interactions

Gene–environment interactions modulate the disposition to excessive alcohol intake. Environmental factors are implicated by the observation that early social isolation stress was followed by (1) low levels of CSF 5-HIAA concentrations, (2) a high availability of brainstem serotonin transporters, (3) reduced drug-elicited GABAergic sedation, and (4) increased alcohol intake in a free choice paradigm (Doudet *et al.*, 1995; Higley *et al.*, 1996; Heinz *et al.*, 1998a). Variation in the genetic constitution of 5-HTT transporters and GABA<sub>A</sub> receptors appears to result in similar interactions between serotonergic and GABAergic neurotransmission, which mimic stress effects on a phenotypical level: human studies observed that a low response to acute alcohol intake was associated with a 5-HTT genotype that predisposes to high serotonin

**Figure 3** The ascending monoaminergic neurotransmitter systems (serotonin, dopamine and norepinephrine) arise from brainstem nuclei and modulate fast excitatory glutamatergic and inhibitory GABAergic neurotransmission.

transporter availability (Schuckit *et al.*, 1999; Hu *et al.*, 2005; Hinckers *et al.*, 2006). In one of the human studies, a low acute response to alcohol was also associated with an allelic variant, Ser385, of the GABA<sub>Aα6</sub> receptor polymorphism Pro385Ser (Schuckit *et al.*, 1999). Animal experiments have further elucidated potential effects of such genetic variation on acute alcohol effects: in rodents; a single nucleotide mutation in the GABA<sub>Aα6</sub> receptor subunit was associated with the effects of moderate alcohol and benzodiazepine intake on motor impairment (Korpi *et al.*, 1993). Schuckit *et al.* (1999) observed in a pilot study that all human subjects who carried a 5-HTT genotype associated with elevated 5-HTT expression plus the Pro/Ser genotype of the GABA<sub>Aα6</sub> receptor subunit developed alcohol dependence during the decade-long follow-up period. In summary, these animal experiments and human studies suggest that both genetic and environmental (stress) factors interact with central serotonergic neurotransmission and thus affect the balance between GABAergic inhibition and glutamatergic excitation such that low serotonin turnover and high transporter availability reduce the sedative and ataxic effects of acute alcohol intake (Higley *et al.*, 1996; Heinz *et al.*, 1998a; Schuckit *et al.*, 1999).

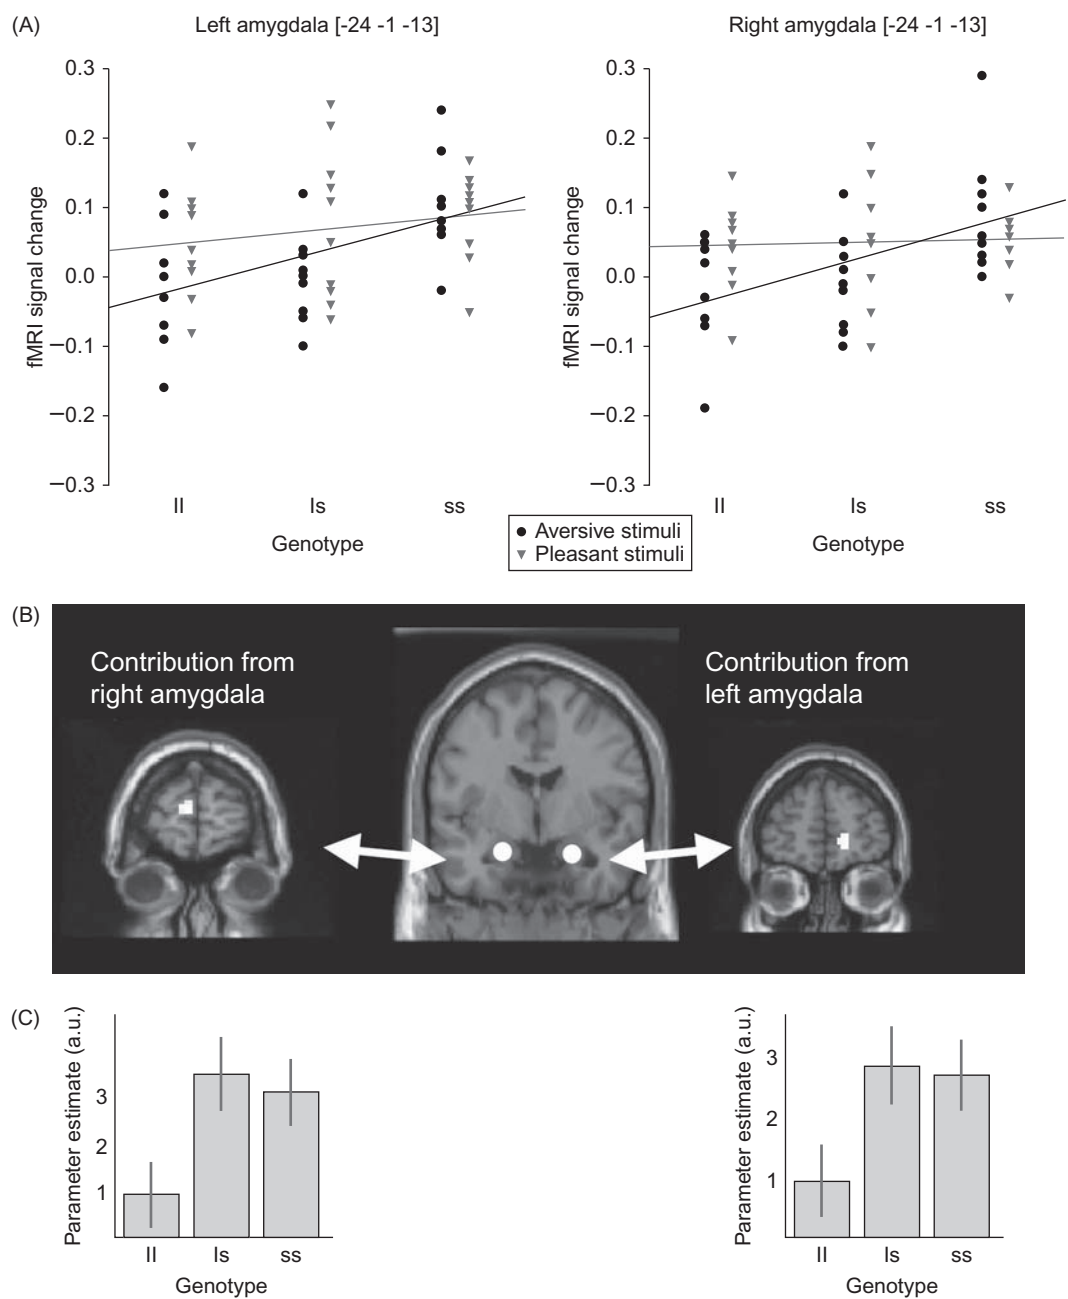

Studies that assessed the potential association of serotonin transporter genotype and the risk to develop alcoholism gave inconsistent results (Gelernter *et al.*, 1997; Edenberg *et al.*, 1998; Sander *et al.*, 1998). These results may be explained by phenocopies of genetic effects on serotonergic neurotransmission – i.e., environmental stress factors appear to mimic genetic effects on serotonin transporters and GABAergic neurotransmission. Bennett and coworkers observed that exposure to early social isolation stress reduced CSF 5-HIAA concentrations in non-human primates only if they carried one or two short alleles of the 5-HTT regulatory unit, while it did not affect CSF 5-HIAA concentrations in carriers of two long alleles (*ll*) of the 5-HTT gene (Bennett *et al.*, 2002). All but one of the primates examined in the imaging study of Heinz *et al.* (1998a) were carriers of this ‘stress-vulnerable’ 5-HTT genotype – i.e., they carried one or two short alleles of the 5-HTT regulatory unit. In this genotype a high availability of brainstem serotonin transporters was found, and can result from stress-induced decreases in central serotonin turnover due to reduced competition between endogenous serotonin and the radioligand for binding at 5-HTT sites (Heinz *et al.*, 1998a, 2004). In the *ll*-genotype, on the other hand, a high availability of central serotonin transporters may be mainly due to genetic factors directly affecting gene expression and function (Lesch *et al.*, 1996). It appears that a common phenotype, high availability of 5-HTT transporters *in vivo*, contributes to a low response to acute alcohol intake, and that this association

is independent of its genetic or environmental causation (Heinz *et al.*, 1998a; Barr *et al.*, 2003).

Altogether, animal experiments suggest that 5-HTT genotype mediates the impact of early social separation stress on the central serotonin turnover rate, and this effect may be mediated by differences in the stress hormone axis (Bennett *et al.*, 2002; Barr *et al.*, 2004). In non-human primates, social isolation stress was associated with a low serotonin turnover rate and associated changes in the availability of brainstem (raphe) serotonin transporters (Higley *et al.*, 1996; Heinz *et al.*, 1998a). Behaviorally, non-human primates with a low serotonin turnover rate and a high availability of brainstem serotonin transporters displayed high levels of anxiety, impulsive aggression, and a low response to alcohol (Higley *et al.*, 1996; Heinz *et al.*, 1998a). Increased aggressiveness and a low response to alcohol were also found in mice lacking the 5-HT<sub>1B</sub> receptor (Coccaro *et al.*, 1989; Saudou *et al.*, 1994). Human studies also suggest that a low serotonin turnover rate is associated with anxious behavior and perceptions of insecurity and threat, which may secondarily contribute to impulsive aggression (Praag, 1977; Meltzer *et al.*, 1994; Knutson *et al.*, 1998). Serotonin function may contribute to negative mood states via modulation of amygdala responses to emotionally negative stimuli. Indeed, in healthy human volunteers amygdala activation elicited by aversive stimuli was modulated by 5-HTT genotype, with carriers of a short allele of the 5-HTT gene displaying more amygdala activation; healthy volunteers carrying this genotype may be able to maintain limited levels of negative mood states because aversive stimuli also elicit increased activation of the medial prefrontal cortex, which can contribute to emotion regulation (Heinz *et al.*, 2005; Pezawas *et al.*, 2005; Figure 4).

However, stress effects may interfere with this prefrontal–limbic connectivity. In human studies, 5-HTT *s*-carriers who had experienced a high number of traumatizing events displayed a higher risk of developing negative mood states such as major depression (Caspi *et al.*, 2003). Also in primate studies, 5HTT *s*-carriers were specifically vulnerable to social isolation stress, which induced significant reductions in the central serotonin turnover rate (Bennett *et al.*, 2002).

Gender-specific effects on the interaction between early social isolation stress, serotonin transporter genotype and HPA axis were implicated in studies among non-human primates (Barr *et al.*, 2004). Female and male rhesus monkeys were either raised without their mothers by their peers (peer-raised, PR), or grew up with their mothers (mother-raised, MR). When subjected to complete social isolation, female primates displayed an increase in cortisol concentrations in *s*-carriers compared with *ll*-homozygotes only if they were previously raised without

**Figure 4** (A) 5-HTT genotype modulates amygdala activation elicited by aversive versus neutral (black) but not by pleasant versus neutral (red) pictures. (B) Assessment of bilateral functional connectivity between the amygdala and medial prefrontal cortex (PFC). In healthy control subjects, 5-HTT genotypes with increased amygdala activation elicited by aversive cues also showed increased functional connectivity between the amygdalae and medial prefrontal cortex (Brodmann's area: BA10), which may limit effects of limbic stimulation and facilitate cortical control. (C) Parameter estimates of connectivity between the amygdala and medial PFC modulated by 5-HTT genotype: risk allele (s-allele) carriers display increased parameter estimates for functional connectivity. (B) Modified by permission from Macmillan Publishers Ltd (*Psychiatry Research*, Heinz *et al.*, ©2005).

their mothers (PR) – i.e., if they had experienced early adversity in the form of social separation stress – while male *s*-carriers displayed increased ACTH concentrations during social isolation independent of whether they were PR or MR.

Altogether, it appears that 5-HTT genotype modulates stress exposure and stress hormone effects on 5-HTT expression and function. Specifically, stress-related alterations in serotonin turnover and transporter availability may interfere with the 5-HTT genotype-driven

interaction between the medial prefrontal cortex and the amygdala, thus impairing prefrontal emotional control. Studies in humans and non-human primates suggest that gender effects may influence whether serotonin dysfunction results in negative mood states or impulsive aggression – an observation that is particularly relevant for clinical depression, which is more frequently observed in women than in men (Heinz *et al.*, 1998a; Barr *et al.*, 2004).

### Serotonin and major depression

Serotonin dysfunction has long been the focus of research on the neurobiological correlates of major depression. Asberg *et al.* (1976, 1984) showed that serotonin turnover rates are reduced in major depression, and increase with recovery. A series of studies measured serotonin transporter availability and function, because several antidepressive drugs block serotonin reuptake and thus alleviate negative mood states (Pirker *et al.*, 1995; Meltzer *et al.*, 1997; Meyer *et al.*, 2004a). Single photon emission computed tomography (SPECT) imaging studies in major depression (Malison *et al.*, 1998; Staley *et al.*, 2006) and seasonal affective disorder (Willeit *et al.*, 2000) revealed a reduction in binding of the radioligand [ $^{123}$ I] $\beta$ -CIT to 5-HTT in the diencephalon and/or brainstem. However, these first studies used the radioligand  $\beta$ -CIT, which competes with endogenous serotonin for binding to central serotonin transporters (Laruelle *et al.*, 1993; Heinz *et al.*, 2004). Therefore, reduced binding of this radioligand to serotonin transporters could either reflect a true reduction in 5-HTT density or increased extracellular serotonin levels that compete with binding at serotonin reuptake sites. In accordance with this latter hypothesis, a high serotonin turnover rate (as indicated by elevated CSF 5-HIAA concentrations) was negatively correlated with serotonin transporter availability measured with radioligand  $\beta$ -CIT in humans and non-human primates (Heinz *et al.*, 1998a, 2002). Interpretation of imaging studies with  $\beta$ -CIT is further complicated by the fact that this radioligand also binds to dopamine and norepinephrine transporters (Laruelle *et al.*, 1993; Seibyl *et al.*, 1994; Rinne *et al.*, 1995); therefore,  $\beta$ -CIT binding to 5-HTT can be assessed only in brain areas such as the brainstem and thalamus, where dopamine transporters are rare and where the radioligand is displaced exclusively by selective serotonin reuptake inhibitors (Laruelle *et al.*, 1993; Pirker *et al.*, 1995, 2000; Heinz *et al.*, 2004).

Parsey *et al.* (2006a, 2006b) used positron emission tomography (PET) and the radioligand [ $^{11}$ C]McN, which displays selective affinity for 5-HTT and is assumed to be not displaceable by endogenous serotonin (Hummerich *et al.*,

2006). They observed reduced midbrain and amygdala 5-HTT availability in a group of 25 patients with major depression. However, this finding was not replicated by Ichimiya *et al.* (2002), who observed unaltered [ $^{11}$ C]McN binding in the midbrain and *increased* binding in the thalamus in a small sample of seven patients with major depression (Ichimiya *et al.*, 2002). Another PET ligand that selectively binds to serotonin transporters is [ $^{11}$ C]DASB (Houle *et al.*, 2000). DASB has a better signal-to-noise ratio than [ $^{11}$ C]McN (Frankle *et al.*, 2004), and is assumed to measure 5-HTT availability independent from synaptic levels of endogenous serotonin (Hummerich *et al.*, 2004). Using DASB and PET in unmedicated patients with major depression and healthy controls, Meyer and coworkers (2004a) observed unaltered binding in various subcortical and cortical regions, including the thalamus and midbrain, with the exception of a subgroup of patients with highly negativistic attitudes that displayed *increased* 5-HTT binding potential. It was suggested that the previously observed reductions in 5-HTT availability in major depression may depend on comorbidity such as anxiety (Meyer, 2007), and on factors like age, gender, smoking status (Staley *et al.*, 2001, 2006) and the genetic constitution of the 5-HTT regulatory region (5-HTTLPR) (Lesch *et al.*, 1996; Heinz *et al.*, 2000; van Dyck *et al.*, 2004; Praschak-Rieder *et al.*, 2007; Reimold *et al.*, 2007). Therefore, discrepancies in the literature may in part be explained by interactions between these covariates (Staley *et al.*, 2006). In a study that compared patients suffering from unipolar major depression with healthy control subjects individually matched for age, smoking status, 5-HTT genotype and gender, the unmedicated patients displayed a significant reduction in their thalamic serotonin transporter (5-HTT) availability (Reimold *et al.*, 2008). In accordance with the hypothesis that serotonin dysfunction is primarily associated with negative mood states, a significant negative correlation was found between serotonin transporter availability in the thalamus and the severity of anxiety (STAI), and, to a lower degree, with the severity of depressed mood (BDI). Furthermore, low serotonin transporter availability in the thalamus was associated with low levels of novelty-seeking (Reimold *et al.*, 2008). These results suggest that reduced serotonin reuptake capacity in the thalamus may interfere with the activity and excitability of thalamic and cortical neurons (McCormick, 1992), and thus contribute to negative mood states such as anxiety, and to a low tendency for seeking new experiences. Therefore, discrepancies between studies using DASB to assess 5-HTT availability in major depression may be explained by different severity of anxiety: Meyer and coworkers (2004b), who did not observe a significant difference in DASB binding in patients suffering from major depression

compared with healthy control subjects, had excluded patients suffering from anxiety disorders, while in the study of Reimold and coworkers (2008) the severity of anxiety rather than depressive mood *per se* was associated with low 5-HTT availability in the thalamus. This interpretation is in accordance with the study of Malison *et al.* (1998), who also reported a negative correlation between anxiety (Hamilton Anxiety Rating Scale) and brainstem  $\beta$ -CIT binding ( $r = -0.32$ ); however, this correlation was not statistically significant ( $n = 15$ ) and 5-HTT availability in other regions was not investigated.

It has been suggested that interactions between gender, age and depression can further help to explain discrepancies in the literature: Staley *et al.* (2006) observed that  $\beta$ -CIT binding was reduced particularly in the diencephalon of younger female patients. Furthermore, several studies did not scan medication-naïve patients, but rather patients suffering from major depression who had been medication-free long enough to avoid direct blockade of serotonin transporters by SSRIs. However, serotonin transporters appear to remain down-regulated after previous exposure to antidepressive medication (Meyer *et al.*, 2001; Benmansour *et al.*, 2002). Therefore, an imaging study in medication-naïve patients matched for gender, 5-HTT genotype and smoking status may help to elucidate interactions between these factors.

In the amygdala, increased activation elicited by aversive stimuli was observed among subjects who carried a 5-HTT genotype that was associated with low serotonin transporter expression (Hariri *et al.*, 2002, 2005; Heinz *et al.*, 2005). Therefore, a low availability of amygdala 5-HTT may directly contribute to negative mood states. However, it is currently not clear whether the assessed 5-HTT genotype exerts its effect via developmental or current expression of 5-HTT in the amygdala or in some other serotonergic brain area (Hansen *et al.*, 1997; Pezawas *et al.*, 2005). Published PET and SPECT studies that revealed reductions in 5-HTT availability in major depression differ with respect to the described anatomical pattern. Reimold *et al.* (2008) and Staley *et al.* (2006) observed 5-HTT reductions in the diencephalons, including the thalamus, but not in the brainstem, while Parsey *et al.* (2006a) observed a significant reduction in SERT availability in midbrain and amygdala, but not in the thalamus. Malison *et al.* (1998) also observed reductions in the brainstem, but did not report on 5-HTT availability in other regions. The study of Reimold and coworkers observed correlations between 5-HTT availability and severity of anxiety in all these regions (Reimold *et al.*, 2008), though group differences may not reach statistical significance due to signal-to-noise issues. The latter may include methodological aspects such as ROI definitions and tracer properties (Frankle *et al.*, 2004), as well

as genotype or smoking status. Reimold and coworkers (2008) showed that explorative voxelwise analysis indeed showed further regions with reduced 5-HTT availability in patients suffering from major depression compared with healthy controls, namely in the midbrain (a cluster that extended into the bilateral thalamus), the left putamen, the right insula, the anterior cingulate and the cingulate gyrus. Altogether, these brain-imaging studies in major depression support the hypothesis that serotonin dysfunction is associated with negative mood states (Heinz *et al.*, 1998a; Knutson *et al.*, 1998; Spillmann *et al.*, 2001; Hasler *et al.*, 2004). Some studies suggest that anxiety is a primary correlate of reduced central 5-HTT availability in major depression (Malison *et al.*, 1998), particularly when patients are matched with healthy control subjects for age, 5-HTT genotype, gender and smoking status. Anxiety may be mediated by 5-HTT effects on limbic processing of emotionally aversive stimuli (Hariri *et al.*, 2002, 2005; Heinz *et al.*, 2005), and clinically relevant depression may manifest when prefrontal control of limbic activation is impaired (Hariri *et al.*, 2002, 2005; Heinz *et al.*, 2005). However, so far no study has directly assessed the interaction between *in vivo* central 5-HTT availability, negative mood states and the processing of affective stimuli in limbic brain areas in health and in major depression.

Depression and anxiety are increased in women with stress hormone dysregulation following severe childhood abuse (Heim *et al.*, 2000). Among patients with anxiety and major depression, dysregulation of the stress hormone axis is a common finding, and appears to be caused at least in part by elevated levels of the hypothalamic neuropeptide corticotrophin releasing hormone (CRH) (Holsboer and Ising, 2008). In alcohol-dependent patients, elevated cortisol levels following detoxification were correlated with a reduction in serotonin transporter availability, which was in turn associated with high levels of anxiety during withdrawal (Heinz *et al.*, 1998a, 1998b, 2002). However, if stress hormone axis activation correlates with negative mood states, it appears counterintuitive that some studies in humans and non-human primates showed a blunted rather than an increased stress hormone response (Barr *et al.*, 2004; Smith *et al.*, 2004) in individuals carrying a serotonin transporter (5-HTT) genotype that is associated with reduced 5-HTT expression, anxiety and dysfunctional amygdala activation elicited by fearful faces (Lesch *et al.*, 1996; Hariri *et al.*, 2005). Moreover, human subjects with this genotype displayed an increased risk to develop clinical depression in cases where they had experienced several severe stressful life events (Caspi *et al.*, 2003). Together, these findings indicate that stress hormones may have differential effects on serotonin transporter availability depending on 5-HTT genotype.

## Serotonin dysfunction and obsessive-compulsive disorder

Several lines of evidence link central serotonergic dysfunction with the manifestation of obsessive-compulsive disorder (OCD) (Swedo and Leonard, 1994). Studies measuring monoamine metabolites in the cerebrospinal fluid (CSF) observed elevated concentrations of the serotonin metabolite 5-hydroxyindoleacetic acid (5-HIAA) in OCD patients (Asberg, 1982; Insel *et al.*, 1985). CSF 5-HIAA concentrations decreased during successful drug treatment of OCD with clomipramine (Thoren *et al.*, 1980), while acute stimulation of 5-HT<sub>2</sub> receptors with m-chloro-phenylpiperazine exacerbated obsessive-compulsive symptoms (Zohar, 1987; Brooks *et al.*, 1998). The important role of serotonergic neurotransmission in OCD is further emphasized by the observation that OCD symptoms are more efficiently reduced when serotonin reuptake is inhibited by clomipramine or selective serotonin reuptake inhibitors (SSRIs) than by the application of norepinephrine reuptake inhibitors (Zohar and Insel, 1987; Goodman *et al.*, 1990).

Dysfunction of fronto-striato-thalamic circuits is implicated in the pathogenesis of both OCD and complex tics (Alexander, 1986; Cummings, 1993). Increased glucose metabolism was found in the orbitofrontal cortex, the head of the caudate and the thalamus of OCD patients compared to healthy controls (Baxter, 1987; Perani *et al.*, 1995). After successful treatment of OCD with behavior therapy or selective serotonin reuptake inhibitors (SSRIs), glucose metabolism decreased in the head of the caudate (Baxter *et al.*, 1992). Ascending fibers from the brainstem, including the serotonergic system, control the firing mode of thalamocortical neurons (McCormick, 1992; Monckton and McCormick, 2002). Therefore, altered serotonin reuptake capacity, for example in the thalamus of OCD patients, may interfere with the role of the thalamus as a 'noise filter' and contribute to overactivity of fronto-striatal-thalamic neurocircuits in OCD. However, fronto-striatal-thalamic overactivity in OCD also appears to involve dopaminergic dysfunction. The dopaminergic and serotonergic systems closely interact, and both animal and human studies support a role for dopamine dysfunction in OCD (van der Wee *et al.*, 2004; Berridge *et al.*, 2005; Hesse *et al.*, 2005). However, studies on dopamine transporter availability in OCD provided disparate results: Hesse *et al.* (2005) described decreased *in vivo* availability of striatal dopamine transporter (DATs) in OCD, while Van der Wee *et al.* (2004) observed an increased DAT availability among patients suffering from OCD. These discrepancies may be due to variation in the DAT genotype that interacts with dopamine transporter availability *in vivo* (van Dyck *et al.*, 2005), comorbid tic disorder (Heinz, 1998c) or other unknown factors. In patients suffering from Tourette's syndrome (TS),

who often display both tics and OCD symptoms, the severity of tics has been positively correlated with dopamine D2 receptor availability in the caudate nucleus (Wolf *et al.*, 1996). Dopaminergic dysfunction may thus primarily contribute to the motor/compulsive aspects of OCD, whereas serotonergic dysfunction may be associated more closely with obsessive ideation (Heinz, 1999).

Several studies measured the *in vivo* availability of serotonin transporters in the brainstem (raphe) area, the center of origin of serotonergic projections, among medication-free OCD patients with positron emission tomography (PET) or single photon emission computed tomography (SPECT) and radioligands that show high affinity for serotonin transporters. However, results have so far been inconsistent: two groups used SPECT and the radioligand [<sup>123</sup>I]β-CIT and observed a significant reduction in serotonin transporter availability in the thalamus/hypothalamus region (Hesse *et al.*, 2005; Zitterl *et al.*, 2007), which was associated with symptom severity. Hesse and coworkers also observed a significant 5-HTT reduction in the midbrain and brainstem of OCD patients (Hesse *et al.*, 2005). On the other hand, Pogarell and colleagues (2003) reported a 25 percent increase in 5-HTT availability in the midbrain using the same ligand, while no significant differences between OCD patients and healthy control subjects were found in two further studies that used either [<sup>11</sup>C]McN 5652 and PET (Simpson *et al.*, 2003) or [<sup>123</sup>I]β-CIT and SPECT (van der Wee *et al.*, 2004). The disparate results may in part be due to the fact that the SPECT radioligand β-CIT competes with endogenous serotonin for binding to central serotonin transporters (Laruelle *et al.*, 1993; Heinz *et al.*, 2004), which resulted in lower radioligand binding in humans and non-human primates with high serotonin turnover as indicated by elevated CSF 5-HIAA levels (Heinz *et al.*, 1998a, 2002). This interaction may be particularly relevant in OCD, where CSF studies suggested significant increases in 5-HIAA concentrations (Asberg, 1982; Insel *et al.*, 1985). On the other hand, *in vivo* studies showed that 5-HTT binding potential measured with [<sup>11</sup>C]DASB was not affected by depletion of the serotonin precursor tryptophan (Praschak-Rieder *et al.*, 2005; Talbot *et al.*, 2005), suggesting that DASB PET can measure 5-HTT independently of synaptic levels of serotonin. Further factors that can modify 5-HTT availability are age, 5-HTT genotype (Lesch *et al.*, 1996; Heinz *et al.*, 2000; Praschak-Rieder *et al.*, 2007; Reimold *et al.*, 2007), gender and smoking status (Staley *et al.*, 2001). One study that accounted for the *individual* combination of gender, genotype and smoking status in OCD patients and healthy controls observed significantly reduced 5-HTT availability in the midbrain and thalamus of OCD patients (Reimold *et al.*, 2007).

Together, these findings suggest that unmedicated OCD patients display reduced thalamus 5-HTT availability when matched for gender, age, 5-HTT genotype and smoking status, compared with healthy control subjects. The imaging studies thus support the hypothesis of serotonergic dysfunction in OCD (Zohar, 1987; Brooks *et al.*, 1998), which may contribute to dysfunctional information processing in fronto-striato-thalamic neurocircuits. Animal experiments and human studies suggest serotonergic dysfunction in the orbitofrontal cortex directly interferes with behavioral flexibility: perseverative responding to a previously rewarded stimulus was provoked by selective serotonin depletion of the prefrontal cortex in non-human primates (Clarke *et al.*, 2004). Serotonin depletion also interfered with further task performance associated with the orbitofrontal cortex in non-human primates (Walker *et al.*, 2006). Studies in humans confirmed that acute serotonin depletion interfered with the function of the dorsomedial prefrontal cortex during reversal learning and negative feedback (Evers *et al.*, 2005). Disruption of dopaminergic or noradrenergic neurotransmission, on the other hand, had no significant effects on reversal learning (Robbins and Roberts, 2007).

Altogether, these findings confirm a prominent role for serotonergic dysfunction in OCD. Unlike in major depression, CSF studies measuring the serotonin metabolite 5-HIAA pointed to an increased rather than a decreased serotonin turnover rate (Asberg and Bertilsson, 1982; Insel *et al.*, 1985). In the brainstem and thalamus of unmedicated OCD patients, serotonin transporters appear to be reduced when compared with healthy controls matched for gender, 5-HTT genotype and smoking status (Reimold *et al.*, 2007). Direct effects of such an alteration in brainstem (raphe) serotonin reuptake capacity have not yet been explored; however, serotonin depletion studies suggest that dysfunction of serotonergic neurotransmission in the orbitofrontal cortex interferes with flexible responding (Robbins and Roberts, 2007), and may thus contribute to obsessive ideation and perhaps also compulsive behavior patterns in OCD.

## Summary and outlook

This review suggests that central serotonin dysfunction is associated with increased anxiety and feelings of threat and insecurity across a wide range of clinical disorders. Anxiety was a direct correlate of reduced serotonin transporter availability in patients suffering from major depression (Malison *et al.*, 1998; Reimold *et al.*, 2008) and alcohol dependence (Heinz *et al.*, 1998a). Impulsive aggression may be a secondary correlate of serotonergic dysfunction due to feelings of threat and insecurity interacting with sex-specific behavior patterns and hormonal

regulation (Knutson *et al.*, 1998; Heinz *et al.*, 2001; Barr *et al.*, 2004). In OCD, an increased rather than decreased serotonin turnover rate may interfere with a thalamic 'noise filter' and with orbitofrontal function during reversal learning, thus contributing to overactivation of fronto-striato-thalamic neurocircuits and behavioral inflexibility (Baxter *et al.*, 1987; Heinz, 1999; Clarke *et al.*, 2008).

Serotonin dysfunction can result from developmentally early social stress factors, and appears to modulate responses to stress and sedative drugs such as alcohol in adolescent and adult humans and non-human primates (Higley *et al.*, 1996; Heinz *et al.*, 1998a; Schuckit *et al.*, 1999; Hinckers *et al.*, 2006). Early epigenetic studies suggest that alterations in DNA methylation may contribute to decreased transcription of 5-HTT mRNA and hence reduced expression of central serotonin transporters (Philibert *et al.*, 2008). Variation in the 5-HTT gene has been shown to correlate with 5-HTT expression and function (Lesch *et al.*, 1996; Heinz *et al.*, 2000) and with limbic and prefrontal responses to aversive stimuli (Heinz *et al.*, 2005; Pezawas *et al.*, 2005; Smolka *et al.*, 2007), and appears to modulate HPA axis activation and the stress-associated risk to develop affective disorders (Caspi *et al.*, 2003; Smith *et al.*, 2004; Jabbi *et al.*, 2007). However, so far we understand only a small part of the picture, and in the future the complex interaction between genetic, epigenetic and environmental factors on serotonin function and dysfunction in specific brain areas can be further elucidated by combined (epi)genetic, endocrinological and imaging studies that assess monoaminergic neurotransmission, sex and stress hormone responses plus functional activation during specific tasks. Such studies may help to develop an individualized therapeutic approach that combines specific behavioral and pharmacological interventions.

<sup>2</sup>*Department of Pharmacology and Therapeutics, University College Cork, Ireland*

<sup>3</sup>*Alimentary Pharmabiotic Centre, University College Cork, Ireland*

**Abstract:** 5-hydroxytryptamine (5-HT, serotonin) is a major neurotransmitter involved in the modulation of behavior, the manifestation of various psychiatric disorders, and is a pharmacological target in the treatment of depression and anxiety disorders. The physiological effects of serotonin are modulated by a variety of proteins that regulate its synthesis, storage, release, uptake and degradation. In addition, serotonin signaling is mediated by at least 14 distinct receptors. Alterations in the expression of genes that regulate the biological effects of serotonin in the brain could alter serotonergic signaling, and thus could ultimately alter behaviors where serotonin has been implicated. The purpose of this chapter is to describe the behavioral consequences of manipulation of genes that regulate serotonergic signaling in rodents and to review analogous genetic association studies in humans that relate to psychiatric disorders, with a particular focus on depression and anxiety disorders. Many of these studies provide supportive evidence of a role for the serotonergic system in various behavioral responses related to depression and anxiety, as well as other psychiatric disorders. In particular, dysfunction of tryptophan hydroxylase, the serotonin transporter (SERT) or 5-HT<sub>1A</sub> receptors can induce behaviors in rodents that are associated with anxiety and depression, and can also alter behavioral responses to antidepressant treatments. Moreover, many of these findings are supported by human genetic association studies. Studies in rodents also suggest that interference with SERT or 5-HT<sub>1A</sub> receptor function specifically during brain development can program anxiety levels and depression in adulthood. Finally, while some evidence suggests that other components of the serotonergic system might also play important roles in these disorders, such findings remain to be refined using genetically modified mice, selective pharmacological tools or human genetic association studies.

**Keywords:** 5-HT, antidepressant, genetically modified mouse, knockout, single-nucleotide polymorphism, tryptophan, SERT, TPH2.

## Introduction

5-hydroxytryptamine (5-HT), or serotonin, is a major neurotransmitter that plays an important role in the modulation of behavior. Serotonin-producing neurons originating in the dorsal and median raphe nuclei of the midbrain (Dahlstrom and Fuxe, 1964) innervate most of the brain, including structures that play important roles in mood regulation as well as the response to stress, which is a precipitating factor of depression and some anxiety disorders (Azmitia and Segal, 1978; Vertes, 1991; Vertes *et al.*, 1999; Sapolsky, 2000; Pittenger and Duman, 2008).

The physiological effects of serotonin are modulated by a variety of proteins that regulate its synthesis, storage, release, uptake and degradation. In addition, serotonin signaling is mediated by at least 14 distinct receptors that are classified into seven groups, 5-HT<sub>1-7</sub> (Figure 1) (Barnes and Sharp, 1999; Hoyer *et al.*, 2002). Considering the multitude of serotonergic receptor subtypes, it is no surprise that serotonin is involved in a diverse array of behavioral functions (Lucki, 1998). Furthermore, serotonin plays a significant role in a wide range of psychiatric disorders, including depression, anxiety disorders, post-traumatic stress disorder, schizophrenia and anorexia nervosa, as well as a range of impulse-related disorders, such as aggression, substance abuse, obsessive-compulsive disorder, gambling and attention-deficit disorder (Lucki, 1998; Gingrich and

**Figure 1** A model of the serotonergic synapse. The biosynthesis of serotonin involves hydroxylation of L-tryptophan by the enzyme tryptophan hydroxylase, to form L-5-hydroxytryptophan (L-5-HTP). L-5-HTP is then decarboxylated by aromatic L-amino acid decarboxylase to form 5-hydroxytryptamine (5-HT; serotonin). Serotonin is packaged into storage vesicles by the vesicular monoamine transporter 2 (VMAT2). Serotonin is removed from the synaptic cleft by the serotonin transporter (SERT). The metabolism of serotonin involves its conversion to 5-hydroxyindoleacetic acid (5-HIAA) by monoamine oxidase (MAO). A variety of presynaptic and postsynaptic serotonin receptors mediate its signaling (5-HT<sub>1-7</sub>).

Hen, 2001). Moreover, serotonin is an important pharmacological target in the treatment of depression and some anxiety disorders (Delgado *et al.*, 1991; Heninger *et al.*, 1996; Vaswani *et al.*, 2003; Lucki and O'Leary, 2004).

Alterations in the expression of genes that regulate the biological effects of serotonin in the brain could alter serotonergic signaling, and thus might ultimately alter behaviors where 5-HT has been implicated. The purpose of this chapter is to describe the behavioral consequences of manipulation of genes that regulate serotonergic signaling in rodents, and to review analogous genetic association studies in humans that relate to psychiatric disorders with a particular focus on depression and anxiety disorders.

### 5-HT synthesis, storage, release, uptake and degradation

Alterations in the expression of genes that regulate synthesis, storage, release, uptake and degradation of 5-HT

in the brain would ultimately result in changes in the synaptic availability of 5-HT. Such changes in gene expression could have important consequences for signaling at various 5-HT receptors, and thus might alter behaviors that are thought to be influenced by the serotonergic system. The following section, which is summarized in Table 1, describes the behavioral effects of genetic manipulation of these genes in mice as well as analogous genetic association studies in humans that relate to anxiety disorders and depression.

### 5-HT synthesis: tryptophan hydroxylase, *Pet-1* and *LIM homeobox transcription factor 1β*

**Preclinical studies** Tryptophan hydroxylase (TPH) is the rate-limiting enzyme for the synthesis of serotonin from L-tryptophan (Grahame-Smith, 1964; Fitzpatrick, 1999; Ruddick *et al.*, 2006). Until recently, it was thought that only one gene (now called *Tph1*) encoded TPH in

<b>5-HT SYNTHESIS</b>		
<b>Animal studies:</b>		
<b><i>Tph 1</i></b>		
Tph 1 knockout		No change (Walther <i>et al.</i> , 2003)
NZW and SWR mice: Tph1 promoter and 3'UTR polymorphisms which result in low 5-HT during development but normal levels in adulthood	Increased immobility in TST and FST (Nakamura <i>et al.</i> , 2006) No response to the SSRI, paroxetine in the FST (Nakamura <i>et al.</i> , 2006)	
<b><i>Tph 2</i></b>		
R439H (equivalent of R441H in human Tph2)	Increased immobility in the TST (Beaulieu <i>et al.</i> , 2008).	Increased anxiety in dark–light emergence test (Beaulieu <i>et al.</i> , 2008)
C1473G	Mice homozygous for G allele do not respond to citalopram in FST (Cervo <i>et al.</i> , 2005) No association with behavioral response to citalopram in TST (Crowley <i>et al.</i> , 2005) Congenic C57BL/6 mice carrying either the C or G allele exhibit similar behavior in TST (Tenner <i>et al.</i> , 2008)	Congenic C57BL/6 mice carrying either the C or G allele exhibit similar behavior in the EPM (Tenner <i>et al.</i> , 2008)
<b><i>Pet-1</i></b>		
Pet-1 knockout		Increased anxiety in the elevated plus maze and open field (Hendricks <i>et al.</i> , 2003)
<b>Human studies:</b>		
<b><i>Tph 1</i></b>		
A218C	No association with major depression (Kunugi <i>et al.</i> , 1999a; Du <i>et al.</i> , 2001; Souery <i>et al.</i> , 2001; Serretti <i>et al.</i> , 2002) Moderates the influence of social support in depressive symptoms (Jokela <i>et al.</i> , 2007)  AA genotype is associated with poor clinical response to SSRIs (Serretti <i>et al.</i> , 2001; Ham <i>et al.</i> , 2007) Generally no association with bipolar disorder (Bellivier <i>et al.</i> , 1998; Kunugi <i>et al.</i> , 1999a; McQuillin <i>et al.</i> , 1999; Reitschel <i>et al.</i> , 2000; Souery <i>et al.</i> , 2001; Serretti <i>et al.</i> , 2002) Association with the clinical response to the mood stabilizer lithium (Serretti <i>et al.</i> , 1999) No association with seasonal affective disorder (Johansson <i>et al.</i> , 2001) No association with premenstrual dysphoric disorder (Magnay <i>et al.</i> , 2006)	No association with panic disorder (Fehr <i>et al.</i> , 2001; Kim <i>et al.</i> , 2006; Maron <i>et al.</i> , 2005) No association with generalized anxiety disorder (Fehr <i>et al.</i> , 2001; You <i>et al.</i> , 2005)
T1095C		No association with obsessive compulsive disorder (Han <i>et al.</i> , 1999)
G-6526A	No association with premenstrual dysphoric disorder (Magnay <i>et al.</i> , 2006)	
G-5806T	No association with premenstrual dysphoric disorder (Magnay <i>et al.</i> , 2006)

**Table 1** (Continued)

	<b>Affective disorders and antidepressant response</b>	<b>Anxiety</b>
rs1799913	A allele associated with major depression (Gizatullin <i>et al.</i> , 2006)	
<b><i>Tph 2</i></b>		
G1463A (R441H)	Associated with severe refractory depression in elderly patients (Zhang <i>et al.</i> , 2005a) No association with major depression (Glatt <i>et al.</i> , 2005; Van Den Bogart <i>et al.</i> , 2005; Zhou <i>et al.</i> , 2005a; Delorme <i>et al.</i> , 2006) No association with bipolar disorder (Zhang <i>et al.</i> , 2005a)	No association with panic disorder (Henningsson <i>et al.</i> , 2007) No association with social phobia (Henningsson <i>et al.</i> , 2007)
rs10748185	No association with unipolar depression (Gizatullin <i>et al.</i> , 2008)	
rs2129575	No association with unipolar depression (Gizatullin <i>et al.</i> , 2008)	
rs1386495	No association with unipolar depression (Gizatullin <i>et al.</i> , 2008)	
rs1386494 A/G	No association with unipolar depression (Gizatullin <i>et al.</i> , 2008)	No association with panic disorder (Maron <i>et al.</i> , 2007).
rs7305115	No association with unipolar depression (Gizatullin <i>et al.</i> , 2008)	
rs4131347 (-C8347G)	No association with unipolar depression (Mann <i>et al.</i> , 2008) No association with bipolar disorder (Mann <i>et al.</i> , 2008)	
rs17110563 (Pro206Ser)	Associated with bipolar disorder (Cichon <i>et al.</i> , 2008)	
rs4290270	Associated with bipolar disorder (Harvey <i>et al.</i> , 2007)	
rs1386483 C/T		No association with panic disorder (Maron <i>et al.</i> , 2007)
Various haplotypes	Association with bipolar disorder (Van den Bogaert <i>et al.</i> , 2006; Lin <i>et al.</i> , 2007) Association with unipolar depression (Van den Bogaert <i>et al.</i> , 2006)	Association with early onset OCD (Mossner <i>et al.</i> , 2006)
<b>5-HT STORAGE AND RELEASE</b>		
<b>Animal studies:</b>		
<b><i>VMAT2</i></b>		
VMAT 2 <sup>+/-</sup> mice	Increased immobility in the FST and TST (Fukui <i>et al.</i> , 2007)  Anhedonia (decreased preference for sweet solutions) (Fukui <i>et al.</i> , 2007)  Increased learned helplessness (Fukui <i>et al.</i> , 2007)	No change in open field, light–dark exploration, novelty-suppressed feeding and zero maze (Fukui <i>et al.</i> , 2007)
<b>Human studies:</b>		
<b><i>VMAT2</i></b>		
T440G	No association with bipolar disorder (Gutierrez <i>et al.</i> , 2007)	
C1368T	No association with bipolar disorder (Gutierrez <i>et al.</i> , 2007)	
T2666C	No association with bipolar disorder (Gutierrez <i>et al.</i> , 2007)	
A2683C	No association with bipolar disorder (Gutierrez <i>et al.</i> , 2007)	

**Table 1** (Continued)

	Affective disorders and antidepressant response	Anxiety
A745G	No association with bipolar disorder (Gutierrez <i>et al.</i> , 2007)	
Haplotype: T allele of rs363399 with C allele of rs4752045	Reduced risk of depression (Christiansen <i>et al.</i> , 2007)	
Haplotypes: 2666T-2683A-745G (TAG) and 2666C-2683C-745A (CCA)	Higher frequency in bipolar disorder (Gutierrez <i>et al.</i> , 2007)	
Haplotypes: 666T-2683C-745A (TCA) and 2666C-2683A-745G (CAG)	Less common in bipolar disorder patients than controls (Gutierrez <i>et al.</i> , 2007)	
<b>5-HT REUPTAKE</b>		
<b>Animal studies:</b>		
<b>SERT</b>		
SERT knockout mice on 129S6 background	Antidepressant-like reduction in immobility in the TST (Holmes <i>et al.</i> , 2002a; Lira <i>et al.</i> , 2003)	No change in anxiety in the open field or in the elevated plus maze (Lira <i>et al.</i> , 2003)
	Increased immobility in the FST (Holmes <i>et al.</i> , 2002a; Lira <i>et al.</i> , 2003)	
	Increased latency to feed in novelty-suppressed feeding test and to escape from shock environment (Lira <i>et al.</i> , 2003)	
SERT knockout mice on C57BL/6 background	No change in immobility in the TST or FST upon first exposure (Holmes <i>et al.</i> , 2002a)	Increased anxiety in the open field, elevated plus maze and light–dark test (Holmes <i>et al.</i> , 2003; Zhao <i>et al.</i> , 2006b; Carroll <i>et al.</i> , 2007; Kalueff <i>et al.</i> , 2007a, 2007b)
	Increased immobility in the TST and FST upon repeated testing (Zhao <i>et al.</i> , 2006b; Carroll <i>et al.</i> , 2007; Wellman <i>et al.</i> , 2007)	
	No change in anhedonia as measured in the sucrose preference test (Kalueff <i>et al.</i> , 2006)	
	No response to the SSRI, fluoxetine in the TST (Holmes <i>et al.</i> , 2002a)	
Mutation at C-terminus of SERT in mice on C57BL/6 background	Increased immobility in the TST upon first exposure (Zhao <i>et al.</i> , 2006b)	
SERT-targeting siRNA in adult mouse brain (2 weeks)	Decreased immobility in the FST (Thakker <i>et al.</i> , 2005)	
SERT blockade during early postnatal development and behavioral testing in adulthood	Increased latency to feed in a novel environment (Ansorge <i>et al.</i> , 2008)	Increased latency to feed in a novel environment (Ansorge <i>et al.</i> , 2008)
	Increased latency to drink a sweet solution in a novel environment (Ansorge <i>et al.</i> , 2004, 2008)	Increased latency to drink a sweet solution in a novel environment (Ansorge <i>et al.</i> , 2004, 2008)
	Increased latency to escape from an environment associated with electric shock (Ansorge <i>et al.</i> , 2004, 2008)	
SERT over-expressing mice		Reduced anxiety in elevated plus maze and hyponeophagia (Jennings <i>et al.</i> , 2006)
SERT knockout rat	Increased immobility in the FST (Olivier <i>et al.</i> , 2008)	Higher latency to feed in a novel environment (Olivier <i>et al.</i> , 2008)
	Anhedonia as demonstrated by reduced preference for a sweet solution (Olivier <i>et al.</i> , 2008)	Higher latency to escape from home cage (Olivier <i>et al.</i> , 2008)
	Higher latency to feed in a novel environment (Olivier <i>et al.</i> , 2008)	Increased anxiety in the open field and elevated plus maze (Olivier <i>et al.</i> , 2008)
	Higher latency to escape from home cage (Olivier <i>et al.</i> , 2008)

MAOA (Tg8) (transgenic insertional mutation which inhibits enzyme function)	Reduced basal immobility in the TST (Cases <i>et al.</i> , 1995)	<p>Enhanced cued and contextual fear conditioning (Kim <i>et al.</i>, 1997)</p> <p>Decreased extinction of a conditioned passive avoidance response (Dubrovina <i>et al.</i>, 2006)</p> <p>Reduced nose-poking in the hole board test and reduced exploration in light-dark test (Popova <i>et al.</i>, 2000)</p>

**Table 1** (Continued)

	Affective disorders and antidepressant response	Anxiety
		Reduced social investigation (Vishnivetskaya <i>et al.</i> , 2007)
		Decreased anxiety in the open field (Cases <i>et al.</i> , 1995)
		No change in time spent in light side of light–dark box (Popova <i>et al.</i> , 2000)
MAOA (A863T) mice (Spontaneous mutation)	No change in immobility in the TST (Scott <i>et al.</i> , 2008)	Decreased activity in the open field (Scott <i>et al.</i> , 2008)
<b>Human studies:</b>		
<b>MAOA</b>		
C-A repeat in intron 2	No association with bipolar disorder (Craddock <i>et al.</i> , 1995; Muramatsu <i>et al.</i> , 1997; Furlong <i>et al.</i> , 1999) No association with unipolar depression (Furlong <i>et al.</i> , 1999) No association with unipolar depression (Muramatsu <i>et al.</i> , 1997)	
VNTR in intron 1	No association with bipolar disorder (Craddock <i>et al.</i> , 1995; Muramatsu <i>et al.</i> , 1997)	
Fnu4HI RFLP G/T silent polymorphism at position 941	No association with bipolar disorder (Craddock <i>et al.</i> , 1995; Muramatsu <i>et al.</i> , 1997; Sasaki <i>et al.</i> , 1998; Furlong <i>et al.</i> , 1999) No association with unipolar depression (Furlong <i>et al.</i> , 1999) No association with unipolar depression (Muramatsu <i>et al.</i> , 1997) No association with unipolar depression (Sasaki <i>et al.</i> , 1998) No association with unipolar depression (Tadic <i>et al.</i> , 2003)	T allele is over-represented in generalized anxiety disorder (Tadic <i>et al.</i> , 2003) No association with panic disorder (Tadic <i>et al.</i> , 2003) Association with OCD (Karayiorgou <i>et al.</i> , 1999)
VNTR in promoter	No association with bipolar disorder (Furlong <i>et al.</i> , 1999; Kunugi <i>et al.</i> , 1999b) Less active VNTR associated with unipolar depression (Brummett <i>et al.</i> , 2007) High-activity MAOA gene promoter alleles associated with major depressive disorder in females (Schulze <i>et al.</i> , 2000) Increased frequency of 4-repeat (4R) allele in MDD patients, especially in the female population (Yu <i>et al.</i> , 2005) MDD female patients who were 3R homozygotes had a better response to fluoxetine treatment when compared to 4R carriers (Yu <i>et al.</i> , 2006) No association with unipolar depression (Furlong <i>et al.</i> , 1999) No association with unipolar depression (Gutierrez <i>et al.</i> , 2004) No association with unipolar depression (Kunugi <i>et al.</i> , 1999b) No association with unipolar depression (Muramatsu <i>et al.</i> , 1997)	Higher activity allele is associated with Panic disorder (Deckert <i>et al.</i> , 1999)
30-bp repeat in the MAOA gene promoter (uMAOA)	No association with bipolar disorder (Gutierrez <i>et al.</i> , 2004) No association with depression (Syagailo <i>et al.</i> , 2001)	

vertebrates. However, in 2003 Walther and colleagues reported that two genes, *Tph1* and *Tph2*, which are found on different chromosomes, encode TPH in the mouse. Specifically, they reported that *Tph1* encoded Tph predominantly in the periphery and the pineal gland, while *Tph2* was expressed exclusively in the brain (Walther *et al.*, 2003). This discovery arose following the finding that despite a dramatic reduction of serotonin in the periphery, midbrain serotonin levels were largely intact in *Tph* knockout mice (Walther *et al.*, 2003). These *Tph* (*Tph1*) knockout mice also exhibited anxiety levels similar to those of the wild-type controls (Walther *et al.*, 2003). This breakthrough shifted attention away from the *Tph1* gene to characterizing the role of the *Tph2* gene in behavior and brain disorders.

Recently, a knockin mouse was generated which expresses a rare human variant of *Tph2* (R441H) that is found in some individuals with unipolar depression (Beaulieu *et al.*, 2008). Mice heterozygous or homozygous for this knockin mutation exhibit between 40 and 80 percent reductions in forebrain 5-HT content, increased immobility in the tail suspension test (TST), and a higher latency to enter the bright compartment in the dark–light emergence test, thus suggesting that the mice have depression- and anxiety-like phenotypes, respectively (Beaulieu *et al.*, 2008). Mice homozygous for this mutation also exhibited increased aggression, while neither genotype differed from wild-type controls in a social interaction test or in basal locomotor activity (Beaulieu *et al.*, 2008). Moreover, it was reported that the R441H polymorphism occurred at a higher frequency in a cohort of patients with unipolar major depression compared to control subjects (Zhang *et al.*, 2005a, but see also Glatt *et al.*, 2005; Van Den Bogaert *et al.*, 2005; Zhou *et al.*, 2005a; Delorme *et al.*, 2006). Prior to the generation of this knockin mouse, a single nucleotide polymorphism which replaces C with G at the 1473 position of *Tph2* and thus reduces 5-HT synthesis *in vitro* was reported (Zhang *et al.*, 2004). Mouse strains homozygous for the 1473G allele, namely the BALB/cJ and DBA/2 mouse strains, had reduced serotonin synthesis and tissue content compared to mouse strains homozygous for the 1473C allele, including the 129×1/SvJ and C57BL/6 mouse strains. This finding generated a lot of interest because of reports that BALB/cJ mice exhibited higher levels of anxiety-like behavior compared with other mouse strains (Griebel *et al.*, 2000; Belzung and Griebel, 2001). Following up on these findings, the role of the C1473G *Tph2* polymorphism in the behavioral response to antidepressants was investigated. In contrast to mouse strains homozygous for the C allele, both BALB/cJ and DBA/2 mice (which are homozygous for the G allele) failed to respond to the selective serotonin reuptake inhibitor (SSRI), citalopram, in the forced

swimming test (FST; Cervo *et al.*, 2005). However, this effect appears to be dependent upon the behavioral test employed, because no correlation between this polymorphism and the behavioral response to citalopram was observed in the TST (Crowley *et al.*, 2005). Finally, a role for the C1473G polymorphism has also been described in aggression, with mouse strains homozygous for the G allele being more aggressive than those homozygous for the C allele (Kulikov *et al.*, 2005). Such correlations between the C1473G polymorphism and various behaviors should be interpreted with caution, however, because the reported strain-dependent behaviors could also be a result of other variations in the genetic background. Indeed, it was just recently reported that congenic C57BL/6 mice carrying either the C1473 or G1473 polymorphism have the same levels of TPH activity and brain 5-HT tissue content, as well as similar behaviors in tests of depression- and anxiety-like behavior, thus suggesting that distinct behavioral characteristics between mouse strains may be due to other variations in the genetic background rather than the C1473G *Tph2* polymorphism alone (Tenner *et al.*, 2008).

Despite initial reports that *Tph1* encoded TPH predominantly in the periphery while *Tph2* was expressed exclusively in the brain, emerging reports suggest that *Tph1* may still play an important role in behavior and the brain. *Tph1* mRNA expression has been reported to be equal to that of *Tph2* mRNA expression in many regions of the human brain (Zill *et al.*, 2007). Moreover, while *Tph2* mRNA expression is four-fold higher than *Tph1* mRNA expression in the raphe nuclei, *Tph1* mRNA levels are higher than those of *Tph2* in the human hypothalamus and amygdala, brain regions which are important in the stress response (Zill *et al.*, 2007). While the extent of *Tph1* mRNA translation in the human brain has yet to be confirmed, various human genetic association studies have already established an association of *Tph1* polymorphisms with various psychiatric conditions as well as the response to antidepressant drugs (Serretti *et al.*, 2001; Gizatullin *et al.*, 2006; Ham *et al.*, 2007). Recent studies also suggest that *Tph1* may be important during brain development. *Tph1* is preferentially expressed during mouse brain development, and the resulting protein exhibits higher enzymatic activity than that encoded by *Tph2* when tested in a model of the developing brainstem (Nakamura *et al.*, 2006). New Zealand white and SWR mice, which have common polymorphisms in both the promoter and 3' untranslated region (UTR) of *Tph1*, exhibit reduced 5-HT levels in the raphe nuclei during development but normal levels in adulthood (Nakamura *et al.*, 2006). Interestingly, both of these mouse strains exhibited depression-like behavior in adulthood, as demonstrated by increases in immobility in both the FST and the TST, and were insensitive to the behavioral

effects of the SSRI antidepressant, paroxetine, in the FST (Nakamura *et al.*, 2006). Moreover, peripheral serotonin synthesis by the TPH encoded by *Tph1* in the mouse dam is a critical determinant of normal brain development in her offspring (Cote *et al.*, 2007). Both *Tph1*<sup>+/-</sup> and *Tph1*<sup>-/-</sup> embryos from *Tph1*<sup>-/-</sup> mothers had morphological brain abnormalities compared to embryos of the same genotype which were born to *Tph1* mothers (Cote *et al.*, 2007). Taken together, it appears that *Tph1* may also play an important role in the development of 5-HT neurons and could thus ultimately affect behavior in adulthood.

The behavioral genetics of 5-HT during development is also strongly influenced by specific transcription factors that are required to establish the enzymatic machinery that is necessary for the production and metabolism of 5-HT (Gaspar *et al.*, 2003). These transcription factors are expressed in postmitotic cells, and include the Lim homeobox transcription factor 1β (*Lmx1b*) (Ding *et al.*, 2003) and plasmacytoma expressed transcript 1 (Pet-1). Pet-1 has a unique expression pattern: it is strictly limited to the raphe nuclei, and appears 1 day before serotonergic neurons can be identified. This factor could directly activate the transcription of *Tph* in addition to other genes involved in 5-HT neurotransmission, such as aromatic amino acid decarboxylase (AADC), the 5-HT transporter (SERT) and the vesicular monoamine transporter (VMAT) (Hendricks *et al.*, 1999; Pfaar *et al.*, 2002; Gaspar *et al.*, 2003). The role of developmental serotonin synthesis in anxiety and aggression are further supported by a recent study of mice lacking Pet-1. Adult Pet-1 knockout mice exhibit a 70 percent loss of serotonergic neurons and an 80–85 percent reduction in 5-HT tissue content in multiple brain regions. Moreover, in the serotonergic neurons that do remain, dramatic reductions in tryptophan hydroxylase, SERT and VMAT are observed (Hendricks *et al.*, 2003). These mice exhibit increased aggression as well as increased anxiety in the open field and elevated plus maze (Hendricks *et al.*, 2003). A later study generated *Lmx1b* conditional knockout mice (*Lmx1b*<sup>fl/f</sup>/p) in which *Lmx1b* was only deleted in Pet-1-expressing 5-HT neurons. While the initial generation of central 5-HT neurons appeared normal in these mice, 5-HT-specific markers including *Tph2* mRNA were absent at later stages of development, thus suggesting that *Lmx1b* maintains Pet-1 expression. These *Lmx1b*<sup>fl/f</sup>/p mice survive to adulthood and exhibit normal locomotor activity, and thus may prove to be a useful animal model for examining the roles of central 5-HT in a variety of animal behaviors (Zhao *et al.*, 2006a). In support, it has already been reported that inactivation of *Lmx1b* in serotonergic neurons results in enhanced contextual fear conditioning, a behavior thought to be related to cognitive deficits associated with anxiety (Dai *et al.*, 2008).

**Human studies** Human genetic association studies of both *Tph1* and *Tph2* have been conducted, but the contribution of the *Tph1* gene to brain disorders has been investigated more extensively. Most human genetic associations of the *Tph1* gene have focused on the 218A/C polymorphism. While this polymorphism has not been associated with major depressive disorder (Kunugi *et al.*, 1999a; Du *et al.*, 2001; Souery *et al.*, 2001), other polymorphisms (Gizatullin *et al.*, 2006) and a microsatellite of the *Tph1* gene (Nash *et al.*, 2005) have been reported to be associated with this disorder. Furthermore, it appears that the 218A/C and 779A/C polymorphisms moderate the influence of social support on depressive symptoms (Jokela *et al.*, 2007). Moreover, the 218A/C polymorphism appears to play an important role in the response to antidepressant drugs, with the A/A genotype being associated with a poor clinical response to various SSRI antidepressant drugs (Serretti *et al.*, 2001; Ham *et al.*, 2007). The contribution of the 218A/C polymorphism to susceptibility to bipolar disorder has also been investigated, with the majority of studies reporting a lack of association (Bellivier *et al.*, 1998; Kunugi *et al.*, 1999a; McQuillin *et al.*, 1999; Rietschel *et al.*, 2000; Souery *et al.*, 2001; Serretti *et al.*, 2002) but interestingly an association with the clinical response to the mood-stabilizer lithium has been reported (Serretti *et al.*, 1999). Similarly, a lack of association of various other SNPs of the *Tph1* gene has also been reported in bipolar disorder (Lai *et al.*, 2005).

The contribution of the 218A/C polymorphism to risk for suicide has also been investigated. While some studies including two meta-analyses reported an over-representation of the A allele in suicide attempters or victims (Abbar *et al.*, 2001; Rujescu *et al.*, 2003; Bellivier *et al.*, 2004), many original investigations have reported a lack of association of suicide with this polymorphism (Kunugi *et al.*, 1999a; Bennett *et al.*, 2000; Ono *et al.*, 2000; Zalsman *et al.*, 2001; Lalovic and Turecki, 2002; Ohtani *et al.*, 2004; Stefulj *et al.*, 2005).

For the most part, studies have reported a lack of association of the 218A/C polymorphism and other *Tph1* polymorphisms with various anxiety disorders, including panic disorder (Fehr *et al.*, 2001; Maron *et al.*, 2005; Kim *et al.*, 2006), generalized anxiety disorder (Fehr *et al.*, 2001; You *et al.*, 2005) and obsessive-compulsive disorder (Han *et al.*, 1999). Similarly, a lack of association of various *Tph1* gene polymorphisms has been reported for many other disorders, including anorexia nervosa (Han *et al.*, 1999), seasonal affective disorder (Johansson *et al.*, 2001), premenstrual dysphoric disorder (Magnay *et al.*, 2006), bulimia (Monteleone *et al.*, 2007), autism (Ramos *et al.*, 2006) and narcolepsy (Fehr *et al.*, 2001).

Given the recent discovery of the *Tph2* gene, only a limited number of genetic association studies of this

gene have been reported. In 2005, a loss-of function SNP (G1463A) in the *Tph2* gene which replaces the arginine441 with histidine was identified and reported to occur more frequently in subjects with unipolar major depression compared to controls (Zhang *et al.*, 2005a), a finding further supported by the depression-like phenotype of knockin mice expressing this mutation (Beaulieu *et al.*, 2008). However, the validity and significance of this study has been cast in doubt by the findings of other groups, who failed to replicate it in much larger cohorts (Glatt *et al.*, 2005; Van Den Bogaert *et al.*, 2005; Zhou *et al.*, 2005a; Delorme *et al.*, 2006). This discrepancy was explained by the original authors as being due to differences in the study groups. All patients involved in the initial study were over 60 years of age, mostly severely ill with many refractory to treatment, while these criteria did not apply to the patients involved in subsequent investigations (Zhang *et al.*, 2005b). This suggests that the G1463A polymorphism in humans may be linked to a very small subset of elderly, severely ill and refractory depressed patients (Delorme *et al.*, 2006; Henningsson *et al.*, 2007). Other studies have also reported a lack of association between unipolar depression and various other *Tph2* polymorphisms (Gizatullin *et al.*, 2008; Mann *et al.*, 2008). However, many other studies do support a possible *Tph2* involvement in depression (and depression-related suicide) through various SNPs in the *Tph2* gene and its upstream promoter region (Zhou *et al.*, 2005b; Ke *et al.*, 2006; Van Den Bogaert *et al.*, 2006; Lopez de Lara *et al.*, 2007). These studies, in addition to findings in animal models, suggest that *Tph2* may be one of many candidate genes that play a contributory role in the development of depression.

Multiple studies have reported that many *Tph2* polymorphisms and haplotypes are associated with bipolar disorder (Van Den Bogaert *et al.*, 2006; Harvey *et al.*, 2007; Lin *et al.*, 2007; Lopez *et al.*, 2007; Cichon *et al.*, 2008), but many other polymorphisms are not associated with this disorder (Zhang *et al.*, 2005a; Mann *et al.*, 2008). Some polymorphisms of the *Tph2* gene have also been associated with anxiety disorders such as obsessive-compulsive disorder (Mossner *et al.*, 2006), while a lack of association of other polymorphisms with panic disorder and social phobia has been reported (Henningsson *et al.*, 2007; Maron *et al.*, 2007). Finally, various *Tph2* polymorphisms have also been associated with aggression (Hennig *et al.*, 2005).

Taken together, it appears that in both human and pre-clinical rodent studies the *Tph2* gene plays a much larger role in behavior and brain disorders than *Tph1*. Although, animal studies suggest that *Tph1* contributes to brain development and sometimes to behavior, human genetic association studies have for the most part reported a lack

of association with many disorders. Nevertheless, a role for *Tph1* in brain and behavior cannot be entirely ruled out because the 218A/C polymorphism is important in the clinical response to SSRI antidepressant drugs. Although the number of human and animal studies investigating the role of *Tph2* in behavior and brain disorders is limited, current evidence suggests that this gene may play a role in unipolar and bipolar depression as well as anxiety disorders.

### **5-HT storage and release: vesicular monoamine transporter 2 (VMAT 2)**

Following 5-HT synthesis, an integral membrane protein of secretory vesicles called the vesicular monoamine transporter 2 (VMAT2) removes serotonin from the cytoplasm and packages it into secretory vesicles which later transport serotonin to the presynaptic terminal for release (Schuldiner *et al.*, 1995). However, VMAT2 is also responsible for the vesicular packaging of other monoamine neurotransmitters as well as serotonin, thus making it difficult to ascertain precisely whether the effects of genetic alterations of VMAT2 on behavior would be specifically due to the loss of vesicular stores of serotonin. Nevertheless, the phenotype of VMAT2 knockout mice and genetic association studies in humans will be described in this chapter.

*VMAT2*<sup>-/-</sup> mice are unable to package monoamines into synaptic vesicles, and as a result all monoamines are rapidly degraded, the consequence of which is severe depletion of 5-HT, dopamine and noradrenaline. These mice are hypoactive, prone to hypothermia, exhibit severe growth retardation, and most die within a few days after birth (Wang *et al.*, 1997). However, heterozygous *VMAT2* mice are viable, and show changes in depression-like behavior in adulthood. Specifically, these mutant mice exhibit a modest increase in immobility in both the TST and FST, and this immobility is reversed by antidepressant treatment (Fukui *et al.*, 2007). *VMAT2*<sup>+/-</sup> mice are anhedonic, as indicated by a loss of sucrose preference, and also demonstrate increased learned helplessness and increased stress-induced release of corticosterone, thus further supporting a depression-like phenotype (Fukui *et al.*, 2007). In tests of anxiety including the open field, light-dark exploration, novelty-suppressed feeding and zero maze, mutant mice behaved similarly to their wild-type counterparts. Taken together, these findings suggest that *VMAT2*<sup>+/-</sup> mice demonstrate a depressive-like phenotype which is devoid of anxiety-like behaviors.

Few human genetic association studies on *VMAT2* have been published. However, several haplotypes of *VMAT2* polymorphisms have been associated with depression

(Christiansen *et al.*, 2007) and bipolar disorder (Gutierrez *et al.*, 2007), and some of the behaviors related to these disorders have been reported to be altered in *VMAT2* mice as described above. Further characterization of *VMAT2* in human psychiatric genetic studies and animal behavioral studies is eagerly awaited.

### ***5-HT reuptake from the synaptic cleft: the serotonin transporter (SERT)***

The serotonin transporter (SERT) is the principal mechanism for the removal of serotonin from the synaptic cleft (Murphy *et al.*, 2004; Blakely *et al.*, 2005). Studies on rodents either over-expressing or lacking functional serotonin transporters have largely focused on behaviors associated with anxiety and depression. This is due in large part to the clinical use of drugs that selectively block the serotonin transporter (SSRIs) in the treatment of depression and some anxiety disorders.

**Preclinical studies** It is now very clear that the genetic background strain of a rodent can markedly influence behavior (Crawley *et al.*, 1997; Jacobson and Cryan, 2007). The SERT knockout mouse has been bred on two different inbred background strains, and this has had some important consequences in defining some of the phenotypes of SERT knockout mice. SERT knockout mice bred onto a 129S6 background exhibit an antidepressant-like reduction in baseline immobility when tested in the TST, but demonstrate increased immobility in the FST (Holmes *et al.*, 2002a; Lira *et al.*, 2003). The increase in FST-induced immobility in SERT knockout mice of the 129S6 background has been suggested to be a result of compromised neuromuscular strength, which likely interferes with their capacity to swim (Holmes *et al.*, 2002a). To further clarify the phenotype of these animals in tests of antidepressant-like activity, these mice have also been tested in the novelty-suppressed feeding test and a shock escape paradigm. In these tests, the SERT knockout mice exhibited an increased latency to feed in a novel environment and increased latency to escape from the shock environment, thus supporting a depression-like phenotype for these animals (Lira *et al.*, 2003).

In contrast to the SERT knockout mice bred on a 129S6 background, SERT knockout mice on a C57BL/6J background do not exhibit changes in baseline immobility upon first exposure to the TST or FST (Holmes *et al.*, 2002a), and do not exhibit changes in a measure of anhedonia, the sucrose preference test (Kalueff *et al.*, 2006). However, they do exhibit higher baseline immobility values in the TST and FST upon repeated testing (Zhao *et al.*, 2006b; Carroll *et al.*, 2007; Wellman *et al.*, 2007),

and when the mutation is restricted to the C-terminus of SERT these mice on a C57BL/6 background exhibit higher baseline immobility upon first exposure to the TST (Zhao *et al.*, 2006b). Furthermore, when tested in the TST, SERT knockout mice on a C57BL/6 background fail to respond to the acute effects of the SSRI antidepressant drug fluoxetine but not the norepinephrine reuptake inhibitor desipramine or the mixed serotonin/norepinephrine reuptake inhibitor imipramine (Holmes *et al.*, 2002a), thus confirming that SERT is a primary target for the acute behavioral effects of fluoxetine. Although the depression-like phenotypes of the SERT knockout mice on a C57BL/6 background are somewhat subtle compared to those on a 129S6 background, recent studies using a SERT knockout rat suggest that constitutive knockout of SERT does indeed result in a depressive-like phenotype. The SERT knockout rat exhibits increased immobility in the FST, anhedonia as demonstrated by reduced preference for a sweet sucrose solution, a higher latency to feed in a novel environment, and a higher latency to escape from their home cage (Olivier *et al.*, 2008).

Overall, data from experiments with SERT knockout rodents suggest that constitutive knockout of the SERT gene results in depression-like behavior. This finding was initially surprising, because chronic treatment with SSRI antidepressants downregulates SERT in both humans and animals and therefore deletion of SERT would be expected to induce an antidepressant-like phenotype. Recently, a number of investigators tackled this conundrum by suggesting that life-long blockade of SERT, particularly during early brain development, could have different consequences to those of prolonged periods of pharmacological SERT blockade during adulthood. Indeed, down-regulation of SERT by intracerebroventricular infusion of SERT-targeting siRNA into the adult mouse brain for 2 weeks decreases immobility in the FST in a manner similar to chronic SSRI treatment, and thus has an antidepressant-like effect (Thakker *et al.*, 2005). In contrast, when blockade of the serotonin transporter (by treatment with various SSRIs) is restricted to early development (postnatal days 4–21), depression-like behaviors, including increased latency to feed in a novel environment (novelty suppressed feeding), increased latency to drink a sweet solution in a novel environment (novelty-induced hypophagia) and an increased latency to escape from an environment associated with an electrical shock, are observed in adulthood (Ansorge *et al.*, 2004, 2008). However, if adult mice are chronically treated with an SSRI and behaviorally tested 2.5 months following the last drug treatment, changes in depression-associated behaviors are not observed (Ansorge *et al.*, 2008). Taken together, these studies suggest that the depression-like

phenotype of SERT knockout mice is a functional consequence of the loss of SERT early in brain development.

SERT knockout mice have also been tested in behavioral tests of anxiety, but once again strain-dependent effects have been reported. SERT knockout mice on a C57BL/6 background exhibit increased anxiety in the open field, elevated plus maze and light–dark test (Holmes *et al.*, 2003; Carroll *et al.*, 2007; Kalueff *et al.*, 2007a, 2007b; Zhao *et al.*, 2006b). In contrast, SERT knockout mice on a 129S6 background do not exhibit any changes in anxiety-like behavior in these tests (Lira *et al.*, 2003). However, SERT knockout rats exhibit increased anxiety levels in the open field and elevated plus maze, thus supporting the hypothesis that constitutive loss of SERT results in an anxious phenotype (Olivier *et al.*, 2008). Moreover, transgenic mice over-expressing human SERT exhibit reduced anxiety, and this effect is reversed by acute administration of the SSRI paroxetine (Jennings *et al.*, 2006). Finally, a recent study suggests that, like the depression phenotype, the anxious phenotype of SERT knockout mice is also a direct consequence of SERT blockade during early postnatal development but not during adulthood (Ansorge *et al.*, 2008). Taken together, animal studies suggest that during early postnatal development, SERT plays an important role in programming anxiety levels in adulthood.

In addition to altered emotional behaviors, SERT knockout mice also exhibit a number of other key behavioral and physiological phenotypes, including late onset obesity (Holmes *et al.*, 2002a; Murphy and Lesch, 2008), reduced basal corticosterone levels (Murphy and Lesch, 2008), enhanced stress-induced ACTH release (Li *et al.*, 1999), sleep abnormalities such as increased duration and number of REM sleep episodes (Wisor *et al.*, 2003; Alexandre *et al.*, 2006), reduced social interaction (Kalueff *et al.*, 2007a), decreased compulsive activity in the marble burying test (Zhao *et al.*, 2006b) and reduced basal locomotor activity in C57BL/6 SERT knockout mice (Holmes *et al.*, 2002b; Zhao *et al.*, 2006b; Kalueff *et al.*, 2007b) but not in 129S6 SERT knockout mice (Lira *et al.*, 2003). Finally, both SERT knockout mice and rats exhibit reduced aggression (Holmes *et al.*, 2002b; Homberg *et al.*, 2007).

**Human studies** Genetic association studies of the serotonin transporter gene in humans have primarily focused on the role of two SERT-function-modifying gene variants, the first of which is an insertion/deletion polymorphism in the promoter region of *SERT* (the serotonin-transporter-gene-linked polymorphic region, 5-HTTLPR) which results in a long (L) and a short (S) allele. The short (S) allele of this insertion/deletion polymorphism confers lower transcriptional activity relative to the long (L) allele. The second variant is a variable

number of tandem repeats (VNTR) polymorphism in functional intron 2, which consists of 9, 10 or 12 repeats (SERTin2:9, 10 or 12) and can display functionality both *in vitro* (Fiskerstrand *et al.*, 1999; Lovejoy *et al.*, 2003; Klenova *et al.*, 2004) and *in vivo* (MacKenzie and Quinn, 1999).

The short variant of the 5-HTTLPR is a contributory risk factor for the development of major depression, an effect which is only clearly observed when the S allele occurs in combination with other genetic or environmental risk factors. While an association between the S allele and unipolar depression has been reported by some studies (Collier *et al.*, 1996; Gutierrez *et al.*, 1998a; Dorado *et al.*, 2007), many other studies, including a meta-analysis, have reported a lack of association (Kunugi *et al.*, 1997; Mendlewicz *et al.*, 2004; Lasky-Su *et al.*, 2005; Bozina *et al.*, 2006; Christiansen *et al.*, 2007; Zaboli *et al.*, 2008). Nevertheless, it appears that the S allele of this polymorphism does confer a risk to the development of depressive symptoms in response to stressful life events (Caspi *et al.*, 2003; Kendler *et al.*, 2005; Brummett *et al.*, 2008). Moreover, the 5-HTTLPR polymorphism also plays a critical role in the clinical response to antidepressant treatments because carriers of the S allele are more likely to be poor responders to SSRIs as well as some other antidepressant treatments (Smeraldi *et al.*, 1998; Rausch *et al.*, 2002; Yu *et al.*, 2002; Benedetti *et al.*, 2003; Arias *et al.*, 2005; Perna *et al.*, 2005; Bozina *et al.*, 2007).

The contribution of the SERTin2 polymorphism to the risk of unipolar depression is unclear, with some studies reporting a lack of association (Kunugi *et al.*, 1997; Hoehe *et al.*, 1998; Lasky-Su *et al.*, 2005) and others reporting an association (Liu *et al.*, 1999; Bozina *et al.*, 2006) particularly if it is part of a haplotype with the 5-HTTLPR polymorphism (Gutierrez *et al.*, 1998a). It has also been reported that carriers of alleles with a low number of repeats of the SERTin2 VNTR polymorphism showed better responses to paroxetine (Bozina *et al.*, 2007). Taken together, studies suggest that some polymorphisms of the SERT gene confer a risk to unipolar depression, particularly when in association with other risk factors for the disorder.

Many studies have investigated the contribution of *SERT* polymorphisms to risk for anxiety disorders. While the short allele of the 5-HTTLPR variant has been associated with anxiety-related traits and anxiety disorders in many studies (Lesch *et al.*, 1996; Melke *et al.*, 2001; You *et al.*, 2005; Denys *et al.*, 2006; Grados *et al.*, 2007), numerous other studies have also reported a lack of association (Billett *et al.*, 1997; Hamilton *et al.*, 1999; Camarena *et al.*, 2001; Lang *et al.*, 2004; Meira-Lima *et al.*, 2004; Samochowiec *et al.*, 2004; Schinka *et al.*,

2004). However, it is important to note that such discrepancies may well be a function of which anxiety traits were measured in a particular study (Schinka *et al.*, 2004). Finally, a neuroimaging study of a brain area associated with anxiety, the amygdala, has suggested that S allele carriers exhibited hyperactivity of this brain region in response to fearful stimuli (Hariri *et al.*, 2002), thus further supporting a role for the S allele of the 5-HTTLPR polymorphism in anxiety disorders. The SERTin2 polymorphism has been associated with obsessive-compulsive disorder (Baca-Garcia *et al.*, 2007), and anxiety-related personality traits (Vormfelde *et al.*, 2006), but not generalized anxiety disorder (You *et al.*, 2005). Moreover, a rare polymorphism in the ninth exon, Ile425Val, has been found in unrelated families with obsessive-compulsive disorder (Ozaki *et al.*, 2003; Wendland *et al.*, 2008). Taken together, genetic association studies suggest an association of *SERT* gene variants with risk for anxiety disorders in humans.

The contribution of the 5-HTTLPR and SERTin2 polymorphisms to the risk for bipolar disorder has been investigated, but conflicting results have been reported. Although many individual studies have reported no association between the 5-HTTLPR polymorphism and bipolar disorder (Kunugi *et al.*, 1997; Ewald *et al.*, 1998; Gutierrez *et al.*, 1998b; Meira-Lima *et al.*, 2005; Mendlewicz *et al.*, 2004), several meta-analysis studies and original investigations have revealed an association with bipolar disorder (Collier *et al.*, 1996; Mynett-Johnson *et al.*, 2000; Rotondo *et al.*, 2002; Anguelova *et al.*, 2003; Cho *et al.*, 2005; Lasky-Su *et al.*, 2005). Conflicting results for the SERTin2 polymorphism in bipolar disorder have also been published with the majority reporting a lack of association (Esterling *et al.*, 1998; Hoehe *et al.*, 1998; Bocchetta *et al.*, 1999; Liu *et al.*, 1999; Saleem *et al.*, 2000; Dimitrova *et al.*, 2002; Lasky-Su *et al.*, 2005).

Taken together, studies from both animals and humans suggest a clear role for SERT in anxiety disorders and the mechanism of action of SSRI antidepressant drugs. While some *SERT* polymorphisms may also contribute to risk for unipolar depression, their contribution may only become apparent when combined with other risk factors for the disorder – for example, stressful life events. Finally, studies in rodents suggest that interference with SERT function during brain development can program anxiety levels and depression in adulthood.

### 5-HT degradation: monoamine oxidase A (MAOA)

Following SERT-mediated 5-HT reuptake into the cell, monoamine oxidase A (MAOA) catalyzes the oxidative

deamination of serotonin (Youdim *et al.*, 2006). However, MAOA also metabolizes monoamines other than serotonin, including norepinephrine and dopamine, thus making it difficult to ascertain the exact role of MAOA-induced serotonin metabolism in behavioral phenotypes. Nevertheless, mice lacking functional MAOA exhibit behavioral traits that would be expected by the increased availability of serotonin. Moreover, these mice exhibit a nine-fold increase in brain 5-HT levels and lowered concentrations of its metabolite 5-HIAA, but the only a two-fold increase in brain norepinephrine levels (Cases *et al.*, 1995; Popova *et al.*, 2001). The predominant behavioral feature of MAOA-deficient mice is increased aggression, and this has been observed in two different MAOA knockout mouse lines (Cases *et al.*, 1995; Vishnivetskaya *et al.*, 2007; Scott *et al.*, 2008). Other phenotypic features include enhanced emotional learning, as evidenced by increased cued and contextual fear conditioning (Kim *et al.*, 1997); decreased memory extinction (Dubrovina *et al.*, 2006); decreased exploratory activity in the open field, light–dark and hole board tests (Popova *et al.*, 2000; Scott *et al.*, 2008); reduced social investigation (Vishnivetskaya *et al.*, 2007); sleep apnoea (Real *et al.*, 2007); and attenuated stress-induced corticosterone release (Popova *et al.*, 2006).

Studies examining behaviors related to anxiety and depression have yielded conflicting results in these mice. While one group reported decreased anxiety in the open field (Cases *et al.*, 1995), another reported no change in the light–dark test (Popova *et al.*, 2000). Similarly, while reduced baseline immobility in the FST has been reported in one MAOA knockout strain (Cases *et al.*, 1995), no changes in baseline immobility in the TST were observed in another MAOA knockout strain (Scott *et al.*, 2008). The ambiguity of these results might be a function of disruptions to other monoaminergic systems such as norepinephrine or dopamine, which are also thought to play a role in these psychiatric disorders (Cryan *et al.*, 2004; O’Leary *et al.*, 2007).

The contribution of *MAOA* gene polymorphisms in humans to susceptibility for mood disorders has been investigated extensively. The majority of studies have reported a lack of association for *MAOA* with bipolar disorder (Craddock *et al.*, 1995; Kawada *et al.*, 1995; Nothen *et al.*, 1995; Muramatsu *et al.*, 1997; Parsian and Todd, 1997; Sasaki *et al.*, 1998; Furlong *et al.*, 1999; Kunugi *et al.*, 1999b; Serretti *et al.*, 2002; Gutierrez *et al.*, 2004). On the other hand, the role of *MAOA* polymorphisms in conferring risk for unipolar depression is less clear, with some studies reporting an association particularly in females (Schulze *et al.*, 2000; Yu *et al.*, 2005; Brummett *et al.*, 2007), and others reporting a lack of association with various polymorphisms (Muramatsu *et al.*, 1997;

Sasaki *et al.*, 1998; Furlong *et al.*, 1999; Kunugi *et al.*, 1999b; Syagailo *et al.*, 2001; Tadic *et al.*, 2003; Gutierrez *et al.*, 2004). An association of *MAOA* with generalized anxiety disorder and obsessive-compulsive disorder has been reported (Karayiorgou *et al.*, 1999; Tadic *et al.*, 2003), while a lack of association has been predominantly reported for panic disorder (Deckert *et al.*, 1999; Hamilton *et al.*, 2000; Tadic *et al.*, 2003). Finally, similarly to the mouse model, *MAOA* polymorphisms have been associated with aggression (Brunner *et al.*, 1993; Manuck *et al.*, 2000).

Taken together, both preclinical and human studies suggest a clear role for *MAOA* in aggression, but the contribution to depression and anxiety disorders remains ambiguous.

## 5-HT receptors

The biological effects of serotonin are mediated by at least 14 distinct receptors that have been classified into seven groups, 5-HT<sub>1-7</sub>, based on their structural, functional and biochemical characteristics (Barnes and Sharp, 1999; Hoyer *et al.*, 2002). The heterogeneity of these receptors is further complicated by various processes such as post-translational modifications and heterodimerization (Hoyer *et al.*, 2002; Bockaert *et al.*, 2006), thus generating further complexity when attempting to identify the role of a given 5-HT receptor in behavior. The following section, which is summarized in Table 2, describes the behavioral effects of genetic manipulation of genes encoding serotonergic receptors in mice, as well as analogous genetic association studies in humans that relate to psychiatric disorders.

### 5-HT<sub>1</sub> receptors

The 5-HT<sub>1</sub> receptor class is comprised of five receptor subtypes, 5-HT<sub>1A</sub>, 5-HT<sub>1B</sub>, 5-HT<sub>1D</sub>, 5-HT<sub>1E</sub> and 5-HT<sub>1F</sub> (Cryan and Leonard, 2000; Hoyer *et al.*, 2002). To date, few studies have examined the roles of 5-HT<sub>1E</sub> and 5-HT<sub>1F</sub> receptors on behavior; therefore, the function of these receptors is not discussed in this chapter.

### 5-HT<sub>1A</sub> receptors

5-HT<sub>1A</sub> receptors are largely distributed throughout the CNS. 5-HT<sub>1A</sub> receptors localized in the raphe nuclei are somatodendritic autoreceptors that inhibit cell firing. 5-HT<sub>1A</sub> receptors are also found postsynaptically in a number of limbic brain regions important in the regulation of emotion, such as the hippocampus (Cryan and Leonard, 2000; Hoyer *et al.*, 2002), thus complicating

attempts to unravel the function of 5-HT<sub>1A</sub> receptors in behavior. However, activation of pre- versus postsynaptic 5-HT<sub>1A</sub> receptors can be distinguished by discrete behavioral changes. Selective activation of postsynaptic 5-HT<sub>1A</sub> receptors induces a behavioral syndrome that comprises a flat body posture, reciprocal forepaw treading and head weaving (Hoyer *et al.*, 2002; Lucki, 1992), while activation of presynaptic receptors induces hyperphagia (Simansky, 1996).

**Preclinical studies** In 1998, three independent groups reported the generation of 5-HT<sub>1A</sub> receptor knockout mice on different genetic backgrounds (Heisler *et al.*, 1998; Parks *et al.*, 1998; Ramboz *et al.*, 1998). The predominant phenotype of these animals is anxiety. 5-HT<sub>1A</sub> knockout mice on various genetic backgrounds exhibit elevated anxiety levels when tested in the open field, elevated zero maze, elevated plus maze, novel-object tests, novelty-suppressed feeding test and the light-dark test (Heisler *et al.*, 1998; Parks *et al.*, 1998; Ramboz *et al.*, 1998; Santarelli *et al.*, 2003; Klemenhagen *et al.*, 2006); in some of these tests, 5-HT<sub>1A</sub> mice demonstrated anxiety levels intermediate to those of wild-type and 5-HT<sub>1A</sub><sup>-/-</sup> mice (Heisler *et al.*, 1998; Ramboz *et al.*, 1998). This anxious phenotype is a direct consequence of the loss of 5-HT<sub>1A</sub> receptors specifically in the forebrain during early postnatal development but not during adulthood, thus suggesting that early postnatal processes are critical determinants of anxiety in adulthood (Gross *et al.*, 2002).

Using fear conditioning paradigms, other studies also support an anxious phenotype in 5-HT<sub>1A</sub> receptor knockout mice. When placed in an environment identical to that where the animal previously received a foot shock, mice exhibit freezing behavior. When placed in this identical environment, 5-HT<sub>1A</sub> receptor knockout mice demonstrated more freezing behavior than wild-type mice (Klemenhagen *et al.*, 2006). Moreover, when the mice were placed in an environment that was similar to the original one but also contained novel cues, the freezing behavior of wild-type but not 5-HT<sub>1A</sub> receptor knockout mice decreased (Klemenhagen *et al.*, 2006). This suggests that 5-HT<sub>1A</sub> receptor knockout mice have an innate inappropriate bias towards threatening cues even in a relatively safe environment – a trait often associated with subsets of anxiety disorders. Furthermore, it was recently demonstrated that selective suppression of neural activity of granule cells in the dentate gyrus of the hippocampus suppresses the freezing response of 5-HT<sub>1A</sub> receptor knockout mice to such ambiguous cues (Tsetsenis *et al.*, 2007). However, it is important to note that the enhanced freezing response observed in the 5-HT<sub>1A</sub> receptor knockout mice in contextual fear conditioning may be dependent upon the background strain of the animal (Groenink

**Table 2** The effect of genetic mutations of serotonin receptors on behaviors associated with depression and anxiety disorders

5-HT receptors	Affective disorders and antidepressant response	Anxiety
<b>5-HT<sub>1A</sub> receptors</b>		
<b>Animal studies:</b>		
5-HT <sub>1A</sub> knockout mice	Decreased immobility in the TST (Heisler <i>et al.</i> , 1998; Mayorga <i>et al.</i> , 2001) Decreased immobility in the FST (Parks <i>et al.</i> , 1998; Ramboz <i>et al.</i> , 1998) Do not respond to SSRI antidepressant drugs in behavioral tests (Mayorga <i>et al.</i> , 2001; Santarelli <i>et al.</i> , 2003) Enhanced stress-induced corticosterone release (Gross <i>et al.</i> , 2000)	Increased anxiety in the open field, elevated plus maze, elevated zero maze, novel object test, novelty suppressed feeding and light–dark test (Heisler <i>et al.</i> , 1998; Parks <i>et al.</i> , 1998; Ramboz <i>et al.</i> , 1998; Gross <i>et al.</i> , 2002; Santarelli <i>et al.</i> , 2003; Klemenhagen <i>et al.</i> , 2006)  Increased freezing behavior in contextual fear conditioning (Klemenhagen <i>et al.</i> , 2006; Tsetsenis <i>et al.</i> , 2007) Resistance to anxiolytic effects of benzodiazepines (Sibille <i>et al.</i> , 2000)
5-HT <sub>1A</sub> over-expression in the forebrain during early development		Reduced anxiety in elevated plus maze (Kusserow <i>et al.</i> , 2004)
<b>Human studies:</b>		
C/G at –1019	C/C genotype carriers showed a better response to fluvoxamine (Serretti <i>et al.</i> , 2004) C/C genotype female patients showed a better antidepressant response to fluoxetine (Yu <i>et al.</i> , 2006) C/C patients showed a better response to TMS (Zanardi <i>et al.</i> , 2007) G/G genotype associated with depression (Lemondé <i>et al.</i> , 2003) No association with risk for depression (Anttila <i>et al.</i> , 2007) G allele carriers associated with personality traits that are linked to depression and anxiety such as neuroticism (Strobel <i>et al.</i> , 2003) Increased frequency in G/G genotype in suicide victims (Lemondé <i>et al.</i> , 2003)	
Gly272Asp	272Asp carriers showed enhanced response to fluvoxamine (Suzuki <i>et al.</i> , 2004) No association with response to fluoxetine (Yu <i>et al.</i> , 2006)	
rs10042486C/C	Showed a better response to fluoxetine, paroxetine and milnacipran (Kato <i>et al.</i> , 2009)

Pro279Leu	No association with bipolar disorder (Erdmann <i>et al.</i> , 1996)	

*et al.*, 2003). Nevertheless, the majority of studies support an anxiety-like phenotype for 5-HT<sub>1A</sub> receptor knockout mice.

In addition to anxious behaviors, 5-HT<sub>1A</sub> receptor knockout mice also exhibit enhanced autonomic changes in response to stresses such as heart rate and body temperature (Pattij *et al.*, 2002) and augmented stress-induced corticosterone release (Gross *et al.*, 2000), as well as a resistance to the anxiolytic effects of benzodiazepines (Sibille *et al.*, 2000). Curiously, these increases in anxiety-like behaviors and autonomic stress responses are accompanied by an antidepressant-like phenotype. 5-HT<sub>1A</sub> receptor knockout mice exhibit decreased immobility in both the TST and FST (Heisler *et al.*, 1998; Parks *et al.*, 1998; Ramboz *et al.*, 1998; Mayorga *et al.*, 2001) without changes in general locomotor activity (Parks *et al.*, 1998;

Ramboz *et al.*, 1998). The reduced immobility in the TST was reversed by pharmacologically-induced depletion of endogenous catecholamines but not serotonin (Mayorga *et al.*, 2001), thus suggesting that the excess serotonin levels induced by the loss of 5-HT<sub>1A</sub> autoreceptors does not mediate the antidepressant-like phenotype. Moreover, 5-HT<sub>1A</sub> receptor knockout mice fail to respond behaviorally to acute or chronic treatment with the SSRIs fluoxetine and paroxetine but respond equally well to some other classes of antidepressant drugs, thus suggesting that 5-HT<sub>1A</sub> receptors play an important role in the behavioral response to at least serotonin-selective antidepressant drugs (Mayorga *et al.*, 2001; Santarelli *et al.*, 2003). Other phenotypic changes observed in 5-HT<sub>1A</sub> receptor knockout mice include sleep abnormalities (Boutrel *et al.*, 2002; Monaca *et al.*, 2003) and impairments in

hippocampal-dependent learning and memory tasks but not in hippocampal-independent or motor memory tasks (Parks *et al.*, 1998; Sarnyai *et al.*, 2000).

The importance of serotonin during brain development in shaping behavioral phenotypes in adulthood has been further demonstrated using mice which temporally over-express the 5-HT<sub>1A</sub> receptor during embryonic and early postnatal development (up to postnatal day 1.5; Kusserow *et al.*, 2004; Bert *et al.*, 2005, 2006). These mice, which over-express 5-HT<sub>1A</sub> receptors predominantly in the dentate gyrus of the hippocampus and outer cortical layers, exhibit reductions in anxiety levels in adulthood, a phenotype opposite to that described previously in the 5-HT<sub>1A</sub> receptor knockout mice (Kusserow *et al.*, 2004). However, these mice also exhibit phenotypes which fail to oppose those of the 5-HT<sub>1A</sub> receptor knockout mice, including impairments in the Morris water maze memory task (Bert *et al.*, 2005), decreased locomotor activity and reduced body temperature (Bert *et al.*, 2006).

**Human studies** Despite intense investigation of the 5-HT<sub>1A</sub> receptor knockout mouse, relatively few studies have examined the association of 5-HT<sub>1A</sub> receptor gene polymorphisms with human behavior and brain disorders. Of the studies conducted, however, the majority have primarily focused on the contribution of 5-HT<sub>1A</sub> receptor gene polymorphisms to the clinical response to antidepressant treatments. In this regard, the main polymorphisms examined include the -1019C/G and Gly272Asp variants. There is convincing evidence for a more favorable response to transcranial magnetic stimulation, fluoxetine and various other chemical antidepressants in patients of the -1019C/C genotype (Lemondé *et al.*, 2004; Serretti *et al.*, 2004; Yu *et al.*, 2006; Zanardi *et al.*, 2007). However, one recent study did report that carriers of the -1019C/C genotype demonstrated a poor response to a variety of antidepressant treatments (Baune *et al.*, 2008). Overall, however, it appears that the -1019C/C genotype is associated with a favorable response to antidepressant drugs. The role of the Gly272Asp variant in the therapeutic effects of antidepressant drugs has also been investigated, with some reporting enhanced response in 272Asp carriers (Suzuki *et al.*, 2004) and others reporting no effect (Yu *et al.*, 2006). Other polymorphisms, including rs10042486C/C, rs6295G/G and rs1364043T/T, have also been associated with a favorable clinical response to antidepressant drugs (Kato *et al.*, 2009). From both animal and clinical studies, it is clear that the 5-HT<sub>1A</sub> receptor plays an important role in the mechanism of antidepressant action.

The contribution of 5-HT<sub>1A</sub> receptor gene polymorphisms to depression, anxiety and suicide has also been investigated, but conflicting results have been reported. In a sample of depressed patients, the -1019G/G genotype

was higher than in controls (Lemondé *et al.*, 2003), and carriers of the G allele were more likely to have personality traits associated with depression and anxiety, such as neuroticism (Strobel *et al.*, 2003). However, others have reported a lack of association between the -1019C/G polymorphism and the risk for depression (Anttila *et al.*, 2007). Finally, an increased frequency of the -1019G/G genotype has been reported in suicide victims (Lemondé *et al.*, 2003), but no other variants have been associated with suicide (Nishiguchi *et al.*, 2002; Ohtani *et al.*, 2004; Videtic *et al.*, 2006).

Taken together, both human and preclinical studies have revealed a role for the 5-HT<sub>1A</sub> receptor in the mechanism of action of several antidepressant treatments. Although animal studies suggest that the 5-HT<sub>1A</sub> receptor is an important modulator of anxiety and depression-like behavior, human studies examining the contribution of polymorphisms in this receptor to mood disorders is lacking and warrants further investigation. Nevertheless, human studies suggest that the 5-HT<sub>1A</sub> receptor can modulate at least some behavioral traits associated with depression and anxiety disorders.

### 5-HT<sub>1B</sub> receptor

5-HT<sub>1B</sub> receptors are primarily expressed in the basal ganglia, striatum and frontal cortex. They are localized on presynaptic 5-HT terminals, where they serve as inhibitory autoreceptors of 5-HT release, as well as on other nerve terminals, where they act as heteroreceptors controlling the release of various neurotransmitters including acetylcholine, glutamate, dopamine, norepinephrine and gamma-aminobutyric acid (Barnes and Sharp, 1999; Cryan and Leonard, 2000; Hoyer *et al.*, 2002).

**Preclinical studies** The 5-HT<sub>1B</sub> receptor knockout mouse has been predominantly characterized for the acquisition and sensitivity to drugs of abuse, antidepressant-like and anxiety behaviors, as well as learning.

In the FST and the TST, male 5-HT<sub>1B</sub> receptor knockout mice exhibit baseline immobility values similar to wild-type mice (Mayorga *et al.*, 2001; Jones and Lucki, 2005), but their behavioral responses to low doses of fluoxetine are enhanced when compared with wild-types in the TST (Mayorga *et al.*, 2001). In contrast, female 5-HT<sub>1B</sub> receptor knockout mice exhibit lower immobility in both the TST and FST when compared to female wild-types, and this effect is mediated by endogenous serotonin levels (Jones and Lucki, 2005). Recently, it was discovered that the cellular localization of 5-HT<sub>1B</sub> receptors is regulated by their interaction with the protein p11 (Svenningsson *et al.*, 2006). Mice that over-express p11

and thus exhibit enhanced 5-HT<sub>1B</sub> receptor function have an antidepressant-like phenotype (Svenningsson *et al.*, 2006). In contrast, p11 knockout mice exhibit a depression-like phenotype and have a diminished response to antidepressant treatments (Svenningsson *et al.*, 2006). Such findings are conflicting with the behavioral phenotype of the 5-HT<sub>1B</sub> receptor knockout mice (Mayorga *et al.*, 2001; Jones and Lucki, 2005), perhaps suggesting that other mechanisms may also exist through which p11 exerts such effects.

Conflicting results on anxiety levels in 5-HT<sub>1B</sub> receptor knockout mice have been reported, with some studies reporting no change in standard measures of anxiety in the elevated plus maze (Parks *et al.*, 1998; Brunner *et al.*, 1999; Malleret *et al.*, 1999; Sibille *et al.*, 2007) or the open field (Sibille *et al.*, 2007) and others reporting reduced anxiety in the open field and the social interaction test (Zhuang *et al.*, 1999; Bouwknecht *et al.*, 2001a). These conflicting results may be due to dual functions of 5-HT<sub>1B</sub> receptors as either autoreceptors at serotonergic terminals or heteroreceptors on non-serotonergic neurons. To investigate whether the 5-HT<sub>1B</sub> autoreceptor mediates anxiety, Clark and colleagues (2002, 2004) used viral-mediated gene transfer to selectively over-express 5-HT<sub>1B</sub> receptors on serotonergic neurons in the rat dorsal raphe nucleus. These rats exhibited increased anxiety in the open field and elevated plus maze, but only when tested following inescapable stress (Clark *et al.*, 2002). These rats also exhibited reduced fear-potentiated startle (Clark *et al.*, 2004) but no changes in the FST (Clark *et al.*, 2002). Together with the reduced anxiety levels reported in some studies of the 5-HT<sub>1B</sub> receptor knockout mice (Zhuang *et al.*, 1999; Bouwknecht *et al.*, 2001a), these results suggest that it is the 5-HT<sub>1B</sub> autoreceptor on serotonergic neurons, and not heteroreceptors, which play the predominant role in anxiety-associated behavior.

The behavior of 5-HT<sub>1B</sub> receptor knockout mice has also been examined in learning and memory tests. In a test of spatial memory, the Morris water maze, 5-HT<sub>1B</sub> receptor knockout mice exhibited superior performance (Malleret *et al.*, 1999), and this facilitation of learning performance was selectively enhanced when the complexity of the task was increased (Buhot *et al.*, 2003a; Wolff *et al.*, 2003). Moreover, it was reported that 5-HT<sub>1B</sub> receptor knockout mice were more resistant to age-related deterioration in spatial memory than wild-types (Buhot *et al.*, 2003b). Taken together, experimental data suggest that the 5-HT<sub>1B</sub> receptor plays an important role in learning and memory.

Other phenotypes of the 5-HT<sub>1B</sub> receptor knockout mice include increased aggression (Saudou *et al.*, 1994; Ramboz *et al.*, 1996), increased body weight (Bouwknecht *et al.*, 2000, 2001b), reduced longevity (Sibille *et al.*, 2007), early onset of age-related motor decline (Sibille *et al.*,

2007), circadian rhythm and sleep abnormalities (Boutrel *et al.*, 1999; Sollars *et al.*, 2006), and increased exploration of a novel object and a novel environment (Malleret *et al.*, 1999; Zhuang *et al.*, 1999).

**Human studies** The most commonly investigated polymorphisms of the human 5-HT<sub>1B</sub> receptor gene include the 861G/C and –161A/T variants. Although the role of these variants has been predominantly investigated in attention deficit hyperactivity disorder (ADHD), suicide substance abuse and dependence, the role of 5-HT<sub>1B</sub> receptor gene polymorphisms in behaviors associated with abnormal emotion has also been investigated. Conflicting reports on the role of the 861G/C polymorphism in aggression have been described, with one group reporting a trend for an increased frequency of the C allele in aggression (Davidge *et al.*, 2004) and another reporting no change (Huang *et al.*, 1999). In general, there was no association between suicide, obsessive-compulsive disorder, bipolar disorder, unipolar depression or antidepressant response and various 5-HT<sub>1B</sub> receptor gene polymorphisms including the 861G/C and –161A/T variants (Nishiguchi *et al.*, 2001; Huang *et al.*, 2003; Rujescu *et al.*, 2003; Hong *et al.*, 2004; Stefulj *et al.*, 2004; Tsai *et al.*, 2004; Videtic *et al.*, 2006; Dickel *et al.*, 2007; Kia-Keating *et al.*, 2007; Shaikh *et al.*, 2008).

Taken together, it is clear from preclinical and human studies that the 5-HT<sub>1B</sub> receptor plays an important role in aggression. However, while animal studies suggest that the 5-HT<sub>1B</sub> receptor may also be an important modulator of depression-like and anxiety behaviors, such findings have yet to be substantiated in human studies.

### 5-HT<sub>2</sub> receptors

This class comprises the 5-HT<sub>2A</sub>, 5-HT<sub>2B</sub> and 5-HT<sub>2C</sub> receptors, which preferentially couple to Gq/11.

#### 5-HT<sub>2A</sub> receptor

5-HT<sub>2A</sub> receptors are primarily located in the cortex, claustrum and basal ganglia (Hoyer *et al.*, 2002).

**Preclinical studies** Constitutive knockout of the 5-HT<sub>2A</sub> receptor inhibits anxiety in a number of conflict-based anxiety paradigms (Weisstaub *et al.*, 2006). When compared to their wild-type counterparts, 5-HT<sub>2A</sub> receptor knockout mice spend more time in the center of a brightly-lit open field and exhibit increased rearing, which reflects risk-type behavior. Furthermore, when tested in the dark–light choice test or elevated plus maze, 5-HT<sub>2A</sub> knockout mice spend more time than the wild-type

controls in risky or anxiogenic areas of the tests – namely, the brightly-illuminated compartment of the dark–light choice test or the open arms of the elevated plus maze. Moreover, when compared with their wild-type counterparts, 5-HT<sub>2A</sub> receptor knockout mice demonstrate a decreased latency to begin feeding in a novel environment (the novelty-suppressed feeding test). These reductions in anxiety are not accompanied by changes in fear-conditioned behavior or antidepressant-like behaviors in either the TST or FST. Importantly, the reduction in anxiety-like behaviors is not a result of alterations in HPA axis activity, locomotor activity or feeding behavior, and the anxiety phenotype can be reversed by specific restoration of cortical 5-HT<sub>2A</sub> receptor expression (Weisstaub *et al.*, 2006). In addition to reduced anxiety, 5-HT<sub>2A</sub> receptor knockout mice also exhibit reduced non-rapid eye movement sleep compared to wild-type controls (Popa *et al.*, 2005). Together, the data suggest that the 5-HT<sub>2A</sub> receptor plays important roles in anxiety and sleep.

**Human studies** Data from the rodent studies suggest that the 5-HT<sub>2A</sub> receptor may play an important role in anxiety; however, the contribution of polymorphisms in this gene to anxiety disorders in humans is less clear. For example, conflicting reports of the association of the –1438G/A polymorphism with obsessive-compulsive disorder have been published, with some studies reporting an association of the G allele (Denys *et al.*, 2006), others suggesting an association of the A allele (Enoch *et al.*, 2001; Walitza *et al.*, 2002), and others still suggesting a lack of association of either allele with the disorder but an association of the A allele with severity of symptoms (Tot *et al.*, 2003). Similarly, conflicting results of the association of the T102C polymorphism with panic disorder have been reported, with some suggesting an association (Inada *et al.*, 2003) and others suggesting a lack of association (Fehr *et al.*, 2001; Rothe *et al.*, 2004). Finally, a lack of association of the T102C polymorphism with generalized anxiety disorder has been reported (Fehr *et al.*, 2001).

In addition to anxiety, the frequency of 5-HT<sub>2A</sub> receptor gene polymorphisms has also been investigated in mood disorders. Although a few studies have reported an association between bipolar disorder and various 5-HT<sub>2A</sub> receptor gene polymorphisms (Chee *et al.*, 2001; Bonnier *et al.*, 2002; Ranade *et al.*, 2003), the majority of studies suggest that there is no association (Arranz *et al.*, 1997; Gutierrez *et al.*, 1997; Mahieu *et al.*, 1997; Blairy *et al.*, 2000; Massat *et al.*, 2000; Tut *et al.*, 2000; Murphy *et al.*, 2001; Ni *et al.*, 2002; Etain *et al.*, 2004). The contribution of 5-HT<sub>2A</sub> receptor gene polymorphisms to unipolar depression is less clear, with some studies reporting an

association (Zhang *et al.*, 1997; Du *et al.*, 2000; Choi *et al.*, 2004; Eley *et al.*, 2004; Christiansen *et al.*, 2007) and others reporting a lack of association (Ohara *et al.*, 1998; Arias *et al.*, 2001a, 2001b; Minov *et al.*, 2001; Anguelova *et al.*, 2003; Oswald *et al.*, 2003). However, many studies have reported that 5-HT<sub>2A</sub> receptor gene polymorphisms are associated with the clinical efficacy of SSRI antidepressant drugs (Choi *et al.*, 2005; Kato *et al.*, 2006; McMahon *et al.*, 2006; Denys *et al.*, 2007).

Although the predominant phenotype of the 5-HT<sub>2A</sub> receptor knockout mice is reduced anxiety, the role of the 5-HT<sub>2A</sub> receptor in anxiety disorders has not been substantiated in human genetics association studies. The most consistent finding of the human genetic association studies was that the 5-HT<sub>2A</sub> receptor plays an important role in the efficacy of antidepressant drugs. However, such studies have not yet been conducted in the 5-HT<sub>2A</sub> receptor knockout mice, thus making it difficult to define the precise role of this receptor in the mechanism of antidepressant action.

### 5-HT<sub>2B</sub> receptor

The function of 5-HT<sub>2B</sub> receptors in the brain remains largely unexplored. This is primarily due to a lack of pharmacological agents that show selectivity for the 5-HT<sub>2B</sub> receptor subtype (Doly *et al.*, 2008). However, there are several pharmacological studies which suggest that this receptor may play a role in anxiety (Kennett *et al.*, 1998) and sleep regulation (Popa *et al.*, 2005). A 5-HT<sub>2B</sub> receptor knockout mouse has also been generated (Nebigil *et al.*, 2000), and this mouse is insensitive to MDMA-induced hyperlocomotion and 5-HT release in the nucleus accumbens and ventral tegmental area (Doly *et al.*, 2008). Whether this mouse exhibits behavioral changes related to psychiatric disorders such as anxiety and depression has not yet been reported.

### 5-HT<sub>2C</sub> receptor

The 5-HT<sub>2C</sub> receptor (formerly 5-HT<sub>1C</sub>) (Baxter *et al.*, 1995) is a postsynaptically located, seven-transmembrane spanning receptor present in highest concentrations in the choroid plexus, but significant densities are also found in the subthalamic nucleus, hypothalamus, hippocampus and amygdala (Mengod *et al.*, 1990). The 5-HT<sub>2C</sub> receptor is believed to have an integral function in the control of many physiological and behavioral responses, including feeding, anxiety, temperature regulation, locomotion, sexual behavior and the occurrence of seizures, in addition to a role in mood disorders (Lucki *et al.*, 1989; Baxter *et al.*, 1995; Cryan and Lucki, 2000; Gurevich *et al.*, 2002; Englander *et al.*, 2005).

**Preclinical studies** One of the most intensely investigated phenotypes of the 5-HT<sub>2C</sub> receptor knockout mouse is its obesity. 5-HT<sub>2C</sub> knockout mice consume more food despite normal satiety responses to leptin administration, and this chronic hyperphagia leads to late-onset obesity (Tecott *et al.*, 1995; Nonogaki *et al.*, 1998). However, it was later reported that this obesity only develops after 6 months of age and without further increases in the level of hyperphagia (Nonogaki *et al.*, 2003). This obesity has been associated with a partial leptin resistance, insulin resistance and impaired glucose tolerance, thus suggesting that disruption of 5-HT<sub>2C</sub> receptor function might play a role in the predisposition to type 2 diabetes (Nonogaki *et al.*, 1998). Furthermore, it has been suggested that an age-dependent decline in the energy cost of physical activity could contribute to the development of late-onset obesity in these mice (Nonogaki *et al.*, 2003).

The role of the 5-HT<sub>2C</sub> receptor in the antidepressant response has also been investigated. While pharmacological studies have reported that 5-HT<sub>2C</sub> receptor antagonists have antidepressant-like effects in a variety of behavioral tests, including the rat FST and the olfactory bulbectomy model (Cryan and Lucki, 2000; Rosenzweig-Lipson *et al.*, 2007), 5-HT<sub>2C</sub> receptor knockout mice do not exhibit such behavior in the TST (Cremers *et al.*, 2004). However, these mice do exhibit enhanced behavioral responses to the antidepressant fluoxetine when tested in the TST (Cremers *et al.*, 2004). Taken together, data suggest that the 5-HT<sub>2C</sub> receptor may be an important target in antidepressant drug development, but more studies are required to elucidate its precise contribution to depression and antidepressant efficacy.

Other phenotypes reported in the 5-HT<sub>2C</sub> receptor knockout mice include reduced aversion to a novel environment (Tecott *et al.*, 1998), alterations in HPA axis activity (Chou-Green *et al.*, 2003a; Heisler *et al.*, 2007), impaired spatial learning in the Morris water maze (Tecott *et al.*, 1998), compulsive-like behavior (Chou-Green *et al.*, 2003b), sleep abnormalities including more wakefulness and enhanced responses to sleep deprivation (Frank *et al.*, 2002), and enhanced susceptibility to spontaneous and chemically- or electrically-induced seizures (Tecott *et al.*, 1995; Applegate and Tecott, 1998).

**Human studies** Similarly to preclinical studies, genetic association studies of the 5-HT<sub>2C</sub> receptor gene have revealed a link between this receptor and body weight in humans. Specifically, the frequency of the Ser allele of the Cys23Ser variant of the 5-HT<sub>2C</sub> receptor gene has been reported to be higher in patients with anorexia nervosa compared to controls (Westberg *et al.*, 2002; Hu *et al.*, 2003). Moreover, the -759C/T

polymorphism has been implicated in the weight gain induced by antipsychotic drug treatment. It is in general agreement that the T allele of this polymorphism is protective against antipsychotic drug-induced weight gain (Reynolds *et al.*, 2002; Ellingrod *et al.*, 2005; Miller *et al.*, 2005; Templeman *et al.*, 2005; De Luca *et al.*, 2007; Ryu *et al.*, 2007), although a lack of association has also been reported (Tsai *et al.*, 2002). In addition, various other polymorphisms of the 5-HT<sub>2C</sub> receptor gene have also been associated with antipsychotic drug-induced weight gain (Mulder *et al.*, 2007). Furthermore, the frequency of the T allele has been reported to be lower in obese women (Pooley *et al.*, 2004), and various other polymorphisms of the 5-HT<sub>2C</sub> receptor gene have been associated with obesity in men (Yuan *et al.*, 2000). Moreover, a recent study reported that cell lines with haplotypes containing the -759T allele demonstrated lower expression of the 5-HT<sub>2C</sub> gene (Buckland *et al.*, 2005), thus suggesting that antipsychotic drug-induced weight gain may be a result of reduced 5-HT<sub>2C</sub> receptor expression. In support, constitutive knockout of the 5-HT<sub>2C</sub> receptor results in hyperphagia and obesity in mice (see above).

The role of 5-HT<sub>2C</sub> receptor gene polymorphisms in mood disorders has also been examined. A significant association between the Ser23 allele and bipolar disorder has been reported, but this is generally restricted to female patients and patients with early onset (Gutierrez *et al.*, 1996, 2001; Oruc *et al.*, 1997; Lerer *et al.*, 2001; Massat *et al.*, 2007). While one study reported an excess of Ser23 carriers in patients with major depressive disorder (Lerer *et al.*, 2001), another reported a lack of association of 5-HT<sub>2C</sub> polymorphisms with depression (Frisch *et al.*, 1999). Finally, a lack of association between suicide and the Cys23Ser polymorphism has been reported (Serretti *et al.*, 2007).

The role of 5-HT<sub>2C</sub> receptor gene polymorphisms has been examined in various other disorders. No association was found with panic disorder (Deckert *et al.*, 2000), sleep apnoea (Sakai *et al.*, 2005) or seasonal affective disorder (Johansson *et al.*, 2001). An association of the -759C/T polymorphism with the clinical response to antipsychotic drugs has been reported (Reynolds *et al.*, 2005), while conflicting reports on the role of the Cys23Ser variant have been published (Sodhi *et al.*, 1995; Malhotra *et al.*, 1996; Rietschel *et al.*, 1997).

Taken together, both preclinical studies and human genetic studies clearly implicate a role for the 5-HT<sub>2C</sub> receptor in eating disorders. While pharmacological and genetic studies in animals suggest that functional 5-HT<sub>2C</sub> receptors might be important in the mechanism of antidepressant action, such findings must be further explored particularly in human studies.

### 5-HT<sub>3</sub> receptor

5-HT<sub>3</sub> receptors differ from the other 5-HT receptors in that they are ligand-gated ion channels. They are found either as homomeric receptors composed of five 5-HT<sub>3A</sub> receptor subunits or as complex heteromers composed of at least one 5-HT<sub>3A</sub> receptor subunit in combination with one or more of the 5-HT<sub>3B</sub>, 5-HT<sub>3C</sub>, 5-HT<sub>3D</sub> and 5-HT<sub>3E</sub> receptor subunits (Barnes and Sharp, 1999; Hoyer *et al.*, 2002; Jensen *et al.*, 2008).

Both 5-HT<sub>3A</sub> receptor knockout mice and 5-HT<sub>3</sub>-over-expressing mice have been generated. However, the phenotype of mice over-expressing the 5-HT<sub>3</sub> receptor has been characterized more extensively. The predominant phenotype of 5-HT<sub>3</sub> receptor-over-expression in mice is enhanced sensitivity to drugs of abuse (Engel *et al.*, 1998; Engel and Allan, 1999; Allan *et al.*, 2001). In addition to changes in sensitivity to drugs of abuse, 5-HT<sub>3</sub> receptor-over-expressing transgenic mice demonstrate a number of other behavioral phenotypes, including enhanced contextual fear conditioning, enhanced exploratory behavior to novel environmental stimuli and decreased anxiety in the elevated plus maze (Harrell and Allan, 2003). Importantly, however, it should be noted that some of the described behavioral characteristics of 5-HT<sub>3</sub> receptor-over-expressing mice are dependent upon the background strain. For example, while the reduced anxiety and enhanced contextual conditioning phenotype of 5-HT<sub>3</sub> receptor-over-expression on a B6SJL/F2 background were recapitulated by 5-HT<sub>3</sub> receptor-over-expression on a C57BL/6J background, no such phenotype was apparent on a DBA/2J background (Metz *et al.*, 2006).

The 5-HT<sub>3A</sub> receptor knockout mice have been characterized in anxiety tests, but conflicting results have been reported. Kelley and colleagues described reductions in anxiety-like behavior in 5-HT<sub>3A</sub> receptor knockout mice when tested in the elevated plus maze, light–dark box and novel object test (Kelley *et al.*, 2003). Similarly, decreased anxiety in the elevated plus maze was reported by Bhatnagar and colleagues, but the same study did not find any differences in anxiety-like behavior in the light–dark test or the open field (Bhatnagar *et al.*, 2004b). Since both over-expression and deletion of the 5-HT<sub>3</sub> receptor generally reduces anxiety, the exact role of the 5-HT<sub>3</sub> receptor in anxiety remains ambiguous.

5-HT<sub>3A</sub> receptor knockout mice also exhibit attenuated stress-induced increases in ACTH when compared to wild-type littermates (Bhatnagar *et al.*, 2004b). Enhanced fear conditioning has been reported in 5-HT<sub>3A</sub> receptor knockout mice (Bhatnagar *et al.*, 2004b), but enhanced fear conditioning has also been reported in 5-HT<sub>3</sub> receptor-over-expressing mice (Harrell and Allan, 2003), thus making it difficult to decipher the exact contribution of

the 5-HT<sub>3</sub> receptor to this form of learning and memory. Finally, deletion of the 5-HT<sub>3</sub> receptor also increases immobility in female but not male mice when tested in the FST, thus suggesting a potential role for this receptor in gender differences in antidepressant-like behaviors (Bhatnagar *et al.*, 2004a).

Human genetic studies of the 5-HT<sub>3</sub> receptor have largely focused on its role in the efficacy of anti-emetic drugs, and few studies have examined its role in human behavior and brain disorders. A lack of association of the C178T 5-HT<sub>3A</sub> receptor gene variant with early onset obsessive-compulsive disorder has been reported (Mossner *et al.*, 2007). However, associations with mood disorders have been reported, with one study reporting differences in the frequency of the C178T variant in bipolar disorder patients compared to controls (Niesler *et al.*, 2001), and more recently polymorphisms in the 5-HT<sub>3B</sub> receptor gene have been associated with major depression (Yamada *et al.*, 2006) and bipolar disorder (Frank *et al.*, 2004).

The results from rodent studies suggest that the 5-HT<sub>3</sub> receptor may play a role in the neurobiology of anxiety; however, as far as we are aware human genetic studies of the 5-HT<sub>3</sub> receptor gene have not yet thoroughly investigated anxiety disorders, although one study did report a lack of association with OCD (Mossner *et al.*, 2007). Finally, while there is some evidence to suggest that the 5-HT<sub>3</sub> receptor may play a role in mood disorders, more exhaustive animal and human studies are required.

### 5-HT<sub>4</sub> receptor

The 5-HT<sub>4</sub> receptor is a postsynaptically located seven-transmembrane spanning receptor present at highest densities in limbic brain areas such as the olfactory tubercles, septum, hippocampus and amygdala as well as the basal ganglia (Bockaert *et al.*, 1997).

Despite the generation of 5-HT<sub>4</sub> receptor knockout mice a number of years ago, little has been reported regarding their behavioral phenotype. However, it has been demonstrated that the 5-HT<sub>4</sub> receptor is required for both stress- and MDMA-induced hypophagia (Compan *et al.*, 2004; Jean *et al.*, 2007), and the absence of MDMA-induced anorexia in 5-HT<sub>4</sub> knockout mice has been replicated by both pharmacological blockade and siRNA-mediated 5-HT<sub>4</sub> receptor knockdown in the nucleus accumbens (Jean *et al.*, 2007). In addition to changes in feeding behavior, decreased reactivity to novelty, increased anxiety and enhanced pentylene-induced seizures have been reported in these mice (Compan *et al.*, 2004). Although the behavior of these mice in behavioral tests of antidepressant activity has yet to be reported,

a recent pharmacological study reported that treatment with 5-HT<sub>4</sub> receptor agonists has antidepressant effects in the FST, olfactory bulbectomy model and the chronic mild stress paradigm (Lucas *et al.*, 2007).

Similarly to animal studies, few studies have examined the role of polymorphisms in the human 5-HT<sub>4</sub> receptor gene in human behavior and brain disorders. Nevertheless, it was recently reported that the 5-HT<sub>4</sub> receptor gene may contribute to genetic predisposition to ADHD and schizophrenia (Suzuki *et al.*, 2003; Li *et al.*, 2006). Finally, several polymorphisms of the 5-HT<sub>4</sub> receptor gene have been associated with bipolar disorder (Ohtsuki *et al.*, 2002).

Since extensive preclinical and human genetic studies of the 5-HT<sub>4</sub> receptor are lacking, the role of this receptor in brain and behavior remains to be more extensively characterized.

### 5-HT<sub>5A</sub> receptor

The 5-HT<sub>5</sub> receptor family consists of two members designated 5-HT<sub>5A</sub> and 5-HT<sub>5B</sub>. To date, the 5-HT<sub>5A</sub> receptor has been identified in the mouse, rat and human. The 5-HT<sub>5B</sub> receptor is also expressed in the mouse and rat, but not in the human where the coding sequence is interrupted by stop codons (Nelson, 2004; Thomas, 2006). Within the CNS, the 5-HT<sub>5A</sub> receptor shows a relatively broad distribution in mouse (Plassat *et al.*, 1992; Matthes *et al.*, 1993), rat (Erlander *et al.*, 1993) and human (Rees *et al.*, 1994; Pasqualetti *et al.*, 1998) brain, including the cerebral cortex, hippocampus, thalamus, hypothalamus, habenula, cerebellum and spinal cord. This widespread mRNA localization pattern contrasts with that reported for the 5-HT<sub>5B</sub> receptor, the mRNA for which appears to be restricted to the hippocampus, habenula and dorsal raphe nucleus in mouse and rat (Erlander *et al.*, 1993; Matthes *et al.*, 1993; Serrats *et al.*, 2004). Pharmacologically, both receptors show their highest affinity for lysergic acid (LSD), which appears to act as a partial agonist at the 5-HT<sub>5A</sub> receptor (Nelson, 2004). In terms of animal behavior, 5-HT<sub>5A</sub> receptor knockout mice exhibit increased exploratory activity in a novel environment but no change in home-cage locomotor activity or anxiety-related behaviors (Grailhe *et al.*, 1999). These mice also demonstrate a reduced locomotor response to LSD, a drug which can produce a psychotic state in humans (Grailhe *et al.*, 1999).

The contribution of 5-HT<sub>5A</sub> receptor polymorphisms to the risk of bipolar and unipolar depression has been investigated. Birkett *et al.*, (2000) reported that the frequency of the T/T genotype of the 12A/T polymorphism and the C allele of the -19G/C polymorphism was higher in unipolar depression; however, a later study did not replicate

these findings (Arias *et al.*, 2001c). Similarly, a protective effect of the G allele of the -19G/C polymorphism was reported in bipolar disorder, but this was not replicated by a later study (Birkett *et al.*, 2000; Arias *et al.*, 2001c). Since wide-scale preclinical and human genetic studies of the 5-HT<sub>5A</sub> receptor are lacking, the role of this receptor in brain and behavior remains to be elucidated.

### 5-HT<sub>6</sub> receptor

5-HT<sub>6</sub> receptors are receiving increasing attention as a potential therapeutic target in mood disorders (Branchek and Blackburn, 2000; Schechter *et al.*, 2005). 5-HT<sub>6</sub> receptors are abundant in limbic and cortical regions, and are positively coupled via G<sub>s</sub> to the AC5 subtype of adenylyl cyclase (Baker *et al.*, 1998; Hamblin *et al.*, 1998). Stimulation of 5-HT<sub>6</sub> receptors in the striatum increases phosphorylation of DARPP-32 via the protein kinase A phosphorylation site (Thr34; Svenningsson *et al.*, 2002), and it is conceivable that some of the biochemical actions of 5-HT<sub>6</sub> receptor activation occur via DARPP-32 phosphorylation. As far as we are aware, 5-HT<sub>6</sub> receptor knockout mice have been generated by the Tecott laboratory (US Patent 6060642) and have been reported to have an anxiety phenotype, but this has not been published in a peer-reviewed journal to date. However, the expression of the receptor in the rat brain has been manipulated by using antisense oligonucleotides or viral-mediated gene transfer. Continuous intracerebroventricular administration of an antisense oligonucleotide against the 5-HT<sub>6</sub> receptor for 3–4 days increased anxiety-like behaviors in rats when tested in the social interaction test and the elevated plus maze (Hamon *et al.*, 1999). However, some pharmacological studies have reported that a 5-HT<sub>6</sub> receptor antagonist reduces anxiety and also affects antidepressant-like behaviors (Svenningsson *et al.*, 2007; Wesolowska and Nikiforuk, 2007, 2008; Wesolowska *et al.*, 2007). 5-HT<sub>6</sub> receptor agonism has also been shown to induce antidepressant-like behavior (Svenningsson *et al.*, 2007). In a more recent study, viral-mediated overexpression of the 5-HT<sub>6</sub> receptor gene in the rat nucleus accumbens prevented conditioned place preference for cocaine, but had no effect on either the acute locomotor response to cocaine or the development of cocaine-induced locomotor sensitization (Ferguson *et al.*, 2008). Other than these studies, the role of the 5-HT<sub>6</sub> receptor remains largely uncharacterized.

In human genetic studies, the role of the C267T polymorphism in the 5-HT<sub>6</sub> receptor gene has been predominantly investigated for association with schizophrenia and response to antipsychotic drugs. While one study reported that the T allele of this polymorphism was associated with

an increased risk for schizophrenia (Tsai *et al.*, 1999), other studies reported a lack of association between this polymorphism as well as other polymorphisms with schizophrenia (Shinkai *et al.*, 1999; Vogt *et al.*, 2000; Ohmori *et al.*, 2001). Similarly, while one study reported that the T/T genotype confers better therapeutic efficacy of the antipsychotic drug risperidone (Lane *et al.*, 2004), this polymorphism was not associated with the efficacy of another antipsychotic drug, clozapine (Masellis *et al.*, 2001). The association of the C267T polymorphism with mood disorders has also been investigated, and reports of increased frequency of the C allele in bipolar disorder (Vogt *et al.*, 2000) and of no association with major depressive disorder (Lee *et al.*, 2005) have been published. Finally, a lack of association with suicide has been reported (Okamura *et al.*, 2005).

Taken together, the use of genetic studies to unravel the role of the 5-HT<sub>6</sub> receptor in behavior remains largely unexplored. The availability of 5-HT<sub>6</sub> receptor knockout animals would significantly aid in the characterization of the role this receptor in behavior and brain disorders.

### 5-HT<sub>7</sub> receptor

The 5-HT<sub>7</sub> receptor is the most recently described 5-HT receptor member (Bard *et al.*, 1993; Lovenberg *et al.*, 1993; Hedlund and Sutcliffe, 2004). Functionally, 5-HT<sub>7</sub> receptor activation increases cyclic AMP formation. In the rodent and human brain, the highest receptor densities are found in the thalamus, hypothalamus (including the supra-chiasmatic nucleus), amygdala, hippocampus, cortex and dorsal raphe (To *et al.*, 1995; Thomas *et al.*, 2002; Varnas *et al.*, 2004). In the CNS, important physiological roles for the 5-HT<sub>7</sub> receptor have been established in thermoregulation and circadian rhythmicity (Lovenberg *et al.*, 1993; Hagan *et al.*, 2000; Glass *et al.*, 2003; Guscott *et al.*, 2003; Hedlund *et al.*, 2003). Moreover, recent pharmacological data suggest a role for 5-HT<sub>7</sub> in antidepressant-related behaviors (Wesolowska *et al.*, 2006; Bonaventure *et al.*, 2007). Such assertions are bolstered by a number of genetic studies. Despite its only recent generation, the 5-HT<sub>7</sub> receptor knockout mouse has been well-characterized. These mice exhibit reduced baseline immobility in both the TST and the FST (Guscott *et al.*, 2005; Hedlund *et al.*, 2005). Irrespective of the already reduced baseline immobility, 5-HT<sub>7</sub> receptor knockout mice still respond to the SSRI citalopram in these tests, thus suggesting that the 5-HT<sub>7</sub> receptor does not play a role in acute behavioral effects of at least this particular SSRI (Hedlund *et al.*, 2005). Consistent with the antidepressant-like phenotype in the TST and the FST, 5-HT<sub>7</sub> receptor knockout mice also exhibit reductions in the frequency and time spent in

REM sleep – an effect often induced by antidepressant treatment (Hedlund *et al.*, 2005). In extracellular recordings from hypothalamic slices of 5-HT<sub>7</sub> receptor knockout mice, 8-OH-DPAT-induced circadian rhythm phase shifts are attenuated, thus suggesting a role for the 5-HT<sub>7</sub> receptor in the regulation of circadian rhythms (Guscott *et al.*, 2005). Disruptions in circadian rhythms are often reported in depression. In addition to their antidepressant-like phenotype, 5-HT<sub>7</sub> receptor knockout mice exhibit reduced stereotypic or compulsive behavior in the marble burying test (Hedlund and Sutcliffe, 2007), impaired contextual fear conditioning and hippocampal LTP (Roberts *et al.*, 2004), but no changes in other forms of hippocampus-dependent learning or motor learning (Roberts *et al.*, 2004; Guscott *et al.*, 2005). Finally, no changes in anxiety or locomotor activity were reported in the 5-HT<sub>7</sub> receptor knockout mice (Roberts *et al.*, 2004).

The association of 5-HT<sub>7</sub> receptor gene polymorphisms with human behavior and brain disorders remains largely unexplored. Early studies did not find any association of the proline279 to leucine amino acid substitution with alcoholism (Pesonen *et al.*, 1998), obesity (Hinney *et al.*, 1999), anorexia nervosa (Hinney *et al.*, 1999), bipolar disorder (Erdmann *et al.*, 1996) or schizophrenia (Erdmann *et al.*, 1996). However, a more recent study reported the association of two SNPs with susceptibility to schizophrenia in a Japanese population (Ikeda *et al.*, 2006).

While animal studies suggest a clear association of the 5-HT<sub>7</sub> receptor in depression- and antidepressant-like behaviors, these phenotypes have yet to be fully investigated in human genetic association studies.

### Summary and concluding remarks

A vast number of both preclinical and human studies provide supportive evidence of a role for the serotonergic system in various behavioral responses related to depression and anxiety, as well as many other psychiatric disorders. In particular, dysfunction of TPH, SERT or 5-HT<sub>1A</sub> receptors can induce behaviors in rodents that are associated with anxiety and depression, and can also alter behavioral responses to antidepressant treatments. Moreover, many of these findings are supported by human genetic association studies. Studies in mice also suggest that interference with SERT or 5-HT<sub>1A</sub> receptor function specifically during brain development can programme anxiety levels and depression in adulthood. Finally, while there is some evidence to suggest that other components of the serotonergic system might also play important roles in such disorders, more extensive investigations using genetically modified mice, selective pharmacological tools or human genetic association studies are warranted.

# Functional Pharmacogenetics of Serotonin Receptors in Psychiatric Drug Action

Olga O. Yevtushenko<sup>1</sup> and Gavin P. Reynolds<sup>\*,2</sup>

<sup>1</sup>*Department of Neuropsychopharmacology, Institute of Pharmacology and Toxicology AMS Ukraine, Kyiv, Ukraine*

<sup>2</sup>*Division of Psychiatry and Neuroscience, Queen's University Belfast, Whitla Medical Building, Belfast, UK*

**Abstract:** There is substantial evidence for the importance of serotonin system dysfunction in the biology of mood, anxiety disorders and psychotic illness, as well as in the behavioral disturbances associated with neurodegenerative disorders. Interactions with serotonin receptors are likely to contribute to the mechanisms of action of many psychiatric drugs. There is substantial individual difference in response to drug treatment – not all patients show benefit, the treatment is often inadequate, and adverse effects of drugs may reduce their tolerability. Genetic factors are likely to contribute substantially to this individual variability; variability in serotonin receptor genes can influence both response to drug treatment and the emergence of adverse effects. This chapter concentrates on the functional pharmacogenetics of the main serotonin receptors involved in psychiatric drug action. The 5-HT<sub>1A</sub>, 5-HT<sub>2A</sub> and 5-HT<sub>2C</sub> receptors are the main focus; however, 5-HT<sub>1B</sub>, 5-HT<sub>4</sub>, 5-HT<sub>6</sub> and 5-HT<sub>7</sub> receptors are also discussed. The genes for these receptors exhibit polymorphisms that in some cases have functional effects on the expression or structure of the gene product. The potential involvement of these functional polymorphisms of serotonin receptor genes in the pharmacological mechanism of psychiatric drug action, notably treatment response and development of side effects, is discussed.

**Keywords:** serotonin receptors, pharmacogenetics, antipsychotics, antidepressants, treatment response, side effects.

## Introduction

It would be difficult to over-emphasize the importance of serotonin systems in the pharmacotherapy of psychiatric disorders. Serotonin appears to be central to the biology of affective and anxiety disorders, and implicated in psychotic disease, as well as having a role in the behavioral disturbances associated with various neurodegenerative disorders. The convergence of pharmacological mechanisms of the antidepressant drugs on serotonergic activity has underpinned the long-established serotonin hypothesis of depression, and the efficacy of many antidepressant drugs in anxiety disorders has also implicated serotonin in these clinical problems. Furthermore, there is a role for serotonin in the effects of antipsychotic drugs. The majority of the second-generation, 'atypical' antipsychotics have a high affinity for 5-HT<sub>2A</sub> receptors; this is considered to contribute to a diminution of certain side effects as well as, possibly, to their symptom response profile. These drugs are

also being used in the treatment of bipolar disorder; again, serotonergic mechanisms are thought to contribute.

Thus, many of the drugs used in the treatment of psychiatric disorders act, directly or indirectly, via serotonin receptors. These receptors include 5-HT<sub>1A</sub>, 5-HT<sub>2A</sub> and 5-HT<sub>2C</sub>; effects at certain other receptors, including 5-HT<sub>1B</sub>, 5-HT<sub>4</sub> and 5-HT<sub>6</sub>, may also be important. This chapter will address the functional pharmacogenetics of these receptors in the context of psychiatric drug action. It will not attempt an in-depth review of the pharmacogenetics of the serotonin receptors – the interested reader will be guided to some articles that do this far more comprehensively – but will attempt to bring together interesting findings that not only contribute to understanding the individual differences in drug response, but also provide clues that give us some insight into underlying mechanisms.

The treatment of psychiatric disorders is often unsatisfactory; the response to treatment is often inadequate, and adverse effects of drugs may reduce their tolerability. These limitations are made worse by the fact they are unpredictable; psychiatric treatment regimes are often a process of trial and error. What underlies this individual

\* Corresponding author  
E-mail: g.reynolds@qub.ac.uk

variability in response to drug treatment is multifactorial; environmental factors – lifestyle, social/home environment, personal history (e.g. development, medical illness, trauma) – may play a part, but it is likely that much of the variability is genetic.

Pharmacogenetics – the study of genetic factors underlying individual variability in effects of drug treatment – has undergone a rapid growth in its application to psychiatric pharmacotherapy research over the past 15 years. A large proportion, if not the majority, of pharmacogenetic studies have addressed genes governing, or influencing, serotonin neurotransmission. The most studied of these is the 5-HT transporter (5-HTT) gene, which has a common polymorphism (the HTTLPR) resulting in a sequence deletion within the promoter region. This is considered to influence the activity of the transporter and, perhaps not surprisingly, is implicated in antidepressant action, as well as being associated with depression (Yu *et al.*, 2002; Caspi *et al.*, 2003; Gonda *et al.*, 2005; Ott *et al.*, 2007). We do not intend to discuss the pharmacogenetics of 5-HTT at any length, it having been reviewed frequently and extensively by others (Alessandro and Kato, 2008; Gerretsen and Pollock, 2008; Kronenberg *et al.*, 2008; Serretti *et al.*, 2005), although as an important and functional polymorphism the HTTLPR will inevitably be mentioned; studies of the psychiatric pharmacogenetics of 5-HT receptors may also include investigation of this polymorphism. In addition, there is substantial regulatory interaction between the various components of synaptic 5-HT neurotransmission, and this can result in effects of a polymorphism within one gene (for example, that for 5-HTT) on other gene products (such as 5-HT receptors). This provides a mechanism that might underlie some gene–gene and gene–environment interactions.

However, this chapter will concentrate on some key 5-HT receptors by discussing their genetic variability and how these genetic polymorphisms may have effects on the function of the gene product. Most importantly, we shall discuss how the pharmacogenetics of 5-HT receptors may provide some further understanding of the mechanisms that involve these receptors in the various effects of drugs used in the treatment of psychiatric disorders.

### Genetic polymorphisms and pharmacogenetic mechanisms

Individual variability of 5-HT receptor genes can influence the gene product, the receptor protein, in several ways. The easiest to understand is, of course, the non-synonymous single nucleotide polymorphism (SNP) in a coding region of DNA that results in an amino acid substitution in the protein. This will influence the structure of the receptor and is likely to affect its function, perhaps

in binding of receptor ligands or in interaction with G proteins. Sequence deletions, SNPs or variations in the length of tandem repeat sequences can occur in the promoter region of the gene and affect binding of transcription factors regulating gene expression; many of the more interesting polymorphisms discussed here are known, or likely, to influence promoter activity. Other effects on gene transcription and translation, perhaps via influences on DNA folding, production of splice variants, RNA stability and editing, etc., can potentially occur from polymorphisms elsewhere in the gene sequence.

The mechanisms underlying genetic association with drug effects can result from a variety of gene–drug interactions. It has recently been suggested that there are four main levels of pharmacogenetic associations (Reynolds, 2007), of which three pharmacodynamic interactions are relevant here. Thus, the genetic polymorphism can affect the primary drug target directly, thereby influencing the immediate physiological response to treatment. Alternatively, it can affect a protein that is secondary to this initial interaction but necessary for the effect of drug on the organism. Finally, it may influence disease pathology or other processes, which may then be more or less responsive to the effects of drug treatment. Understanding which of these processes is important can shed light on the mechanisms of both symptom response to drug treatment and the adverse effects of that treatment.

In the following sections, we discuss some of the serotonin receptors that are involved, or potentially involved, in psychiatric disorders and their treatment. Of these, most effort has focused on the 5-HT<sub>1A</sub>, 5-HT<sub>2A</sub> and 5-HT<sub>2C</sub> receptors, and this chapter will reflect that emphasis. Nevertheless, other subtypes have been studied, although not always with any notable pharmacogenetic finds to date; these too will be briefly reviewed. In each case, we briefly assess their known or potential involvement in psychopharmacological mechanisms and identify some of the more important genetic polymorphisms, with an emphasis on those demonstrating some functionality – i.e., polymorphisms known to influence protein structure (non-synonymous coding region SNPs) or gene transcription. Of course, as implied above, there may be functional effects of particular polymorphisms that are as yet unknown, or there may be SNPs that, while not imparting functional effects themselves, may be in linkage disequilibrium with others that do. This may be apparent from genetic association studies, and some potentially relevant case–control studies in disease will also be mentioned prior to briefly reviewing the pharmacogenetics.

### 5-HT<sub>1A</sub> receptor

The 5-HT<sub>1A</sub> receptor is an inhibitory G-protein-coupled receptor found in the region of origin of 5-HT projections

in the CNS, the raphe nuclei of the brainstem. It acts as an autoreceptor on these serotonergic neurons, where it imparts an inhibitory control over neuronal activity. It is also found postsynaptically in terminal regions such as the hippocampus, cortex and basal ganglia. Its actions are mediated via inhibition of adenylate cyclase activity.

The 5-HT<sub>1A</sub> receptor is the site of action of some anxiolytic drugs, and several other drugs, including some antipsychotics, also have effects at this site. However, its greatest relevance in pharmacotherapeutics is its proposed involvement in the antidepressant efficacy of the selective serotonin reuptake inhibitors (SSRIs). These drugs block reuptake of 5-HT into neurons via the 5-HT transporter, resulting in an increase in extraneuronal 5-HT that can interact with the regulatory somatodendritic 5-HT<sub>1A</sub> receptors in the raphe nuclei. The binding of transmitter to these inhibitory autoreceptors results initially in a decrease in neuronal firing, followed by a compensatory down-regulation of receptor density and a return to normal, or elevated, neuronal activity. Thus, SSRIs have been shown to desensitize somatodendritic autoreceptor sites within a few days of administration (Le Poul *et al.*, 1995) and induce a chronic decrease in hippocampal and cortical (postsynaptic) receptors (Spindelegger *et al.*, 2008). The time taken for these regulatory changes may account for the delay in clinical response to antidepressant treatment.

### Genetic variability

There are reports of polymorphisms in the 5-HT<sub>1A</sub> gene that have been investigated in the context of psychiatric disorders and their treatment. There are multiple polymorphisms in the promoter (5') and 3' regions of the gene, as well as several non-synonymous coding region SNPs, including Ile28Val, Asp272Gly and Pro16Leu. The pharmacological effect of these three, and other amino acid substitutions, has been investigated by Del Tredici *et al.* (2004), and their importance in psychiatric disorders by Drago *et al.* (2008). However, little in the way of meaningful results has come from association studies of 5-HT<sub>1A</sub> receptor coding region polymorphisms, which are generally found at low frequencies, with the minor allele consistently less, and sometimes much less, than 5 percent of the sample. Although the non-exonic polymorphisms have higher frequencies of variability, the only one studied to any great extent is -1019C/G, one of several promoter region polymorphisms. The finding that the 5-HT<sub>1A</sub> receptor gene has a common variant in its promoter sequence (Wu and Comings, 1999) which has yielded a clear molecular mechanism potentially explaining its associations with disease and symptom response to

treatment was a major advance in functional psychiatric pharmacogenetics. This -1019C/G SNP occurs at a binding site for transcription factors; the G allele prevents the binding of inhibitory transcription factors, including the repressor Deaf-1, theoretically resulting in an increase in the expression of 5-HT<sub>1A</sub> autoreceptors with a consequent reduction in 5-HT neuronal transmission (Lemondé *et al.*, 2003). Consistent with this, an apparent, but not significant, increase in 5-HT<sub>1A</sub> receptor PET binding potential associated with the G allele has been reported (Parsey *et al.*, 2006). Interestingly, the effect of the transcription factor is considered to be neuron-specific – contrary to the observation at the presynaptic site, receptor expression in postsynaptic regions is reportedly activated by Deaf-1 and hence diminished by the G allele (Czesak *et al.*, 2006), although the PET findings are not consistent with this *in vitro* observation. Nevertheless, the genotypic differences in receptor expression appear to predispose for depression (Lemondé *et al.*, 2003), as well as anxiety and depression-related personality traits (Strobel *et al.*, 2003). A comprehensive review of associations of this SNP in psychiatric disorders is provided by Drago *et al.* (2008).

We find that this polymorphism can influence receptor expression determined in *post-mortem* human brain tissue (C. L. Dalton and colleagues, unpublished data). Interestingly, a human neuroimaging study did not manage to identify this relationship, but did report an association between the 5-HT transporter HTPR polymorphism and 5-HT<sub>1A</sub> receptor binding in the brain.

### Pharmacogenetics

Genetically determined differences in 5-HT<sub>1A</sub> receptor density or function may thus influence the response to drugs which act directly on 5-HT<sub>1A</sub> receptors or otherwise influence 5-HT neurotransmission, as well as the response to treatment of any neuro- or psychopathology that might involve 5-HT systems. Clearly, the prime candidate for involvement in 5-HT<sub>1A</sub> receptor pharmacogenetics is treatment of depression; here, Lemondé *et al.* (2004) and subsequently several other studies have, fairly consistently, demonstrated that the -1019G allele is associated with a poorer response to treatment with SSRIs and, in some studies, other antidepressant drugs (reviewed in Drago *et al.*, 2008).

The effect on SSRI response is not restricted to depression; our recent study on the initial response of panic disorder to SSRI treatment has also shown a beneficial effect of the C allele (Yevtushenko *et al.*, 2009).

The 5-HT<sub>1A</sub> receptor has also been implicated in the action of the atypical antipsychotic drugs. The effects these drugs have in promoting frontal cortical dopamine release,

considered to be a mechanism contributing to improvement of negative symptoms and mediated primarily via 5-HT<sub>2A</sub> receptor antagonism, requires intact 5-HT<sub>1A</sub> receptors (Díaz-Mataix *et al.*, 2005). Reynolds *et al.* (2006a) have shown that the -1019C/G polymorphism of the 5-HT<sub>1A</sub> receptor gene is strongly associated with changes in both negative features and depressive symptoms after 3 months of initial treatment of first-episode psychosis. The G allele was associated with poorer response of the patients in this study, and this finding was replicated by Wang *et al.* (2008) in an Asian population receiving risperidone treatment.

Of the other SNPs in the 5-HT<sub>1A</sub> receptor gene, the only notable pharmacogenetic finding was that of Gly272Asp associated with response to fluvoxamine with the (few) Asp allele carriers having a significantly poorer response in HAM-D-17 score in a Japanese population (Suzuki *et al.*, 2004). This was not replicated in a study with fluoxetine (Yu *et al.*, 2006). The low frequency of the minor allele in this study limits its value, and the possibility of linkage with another functional polymorphism, such as -1019C/G, cannot be excluded.

### 5-HT<sub>2A</sub> receptor

5-HT<sub>2</sub> receptors are excitatory, primarily postsynaptic, G-protein-coupled receptors, bringing about their effects via stimulation of phospholipase C. Of the two major subtypes, 5-HT<sub>2A</sub> receptors are found in many regions of the brain, where they are located predominantly in the prefrontal cortex, claustrum, olfactory nuclei and basal ganglia; here, they modulate the activity of other neurotransmitters, including glutamate, dopamine, acetylcholine and noradrenaline. Thus, the 5-HT<sub>2A</sub> receptors have been shown to modulate the activation of dopaminergic neurons, enhancing transmitter release in the prefrontal cortex (Bortolozzi *et al.*, 2005) with presumed effects on cognitive function, and in the striatum, where they influence motor behavior.

Thus, 5-HT<sub>2A</sub> receptor inhibition is thought to be the mechanism involved in some of the beneficial effects of atypical antipsychotic drugs on cognitive and negative features of psychotic illness, and in minimizing extrapyramidal side effects. There is also some evidence for their role in antidepressant action; a common consequence of antidepressant drug administration is the down-regulation of 5-HT<sub>2A</sub> receptors. Interestingly, these receptors decrease their expression not only in response to elevated agonist activity, but also following exposure to antagonists such as clozapine (Reynolds *et al.*, 1983). This may relate to the inverse agonism that clozapine and many other 5-HT<sub>2A</sub> antagonists demonstrate; the receptor has a high level of intrinsic activity which can be elevated by

agonists, while these inverse agonists not only, as antagonists, block agonist action, but also decrease the inherent activity of the receptor in the absence of agonist effects (Egan *et al.*, 1998).

### Genetic variability

The substantial sequence variability in the 5-HT<sub>2A</sub> receptor gene has been much studied, particularly in association studies. Of these, the 102T/C polymorphism has been the most intensively investigated. It is located in exon 1 near the promoter region, but is a synonymous polymorphism, and hence does not result in alteration of the amino acid sequence of the receptor protein. The 102T/C is in complete linkage disequilibrium with another polymorphic site of the gene referred to as -1438A/G, which in turn has also been shown to be in linkage disequilibrium with a third polymorphism, -783A/G (Myers *et al.*, 2007). There are other SNPs that have been investigated in association with clinical measures – a silent 516C/T and two non-synonymous SNPs, Thr25Asn and His452Tyr. However, the minor allele frequencies in the European population are 2 percent for 516C/T and Thr25Asn, and 8 percent for His452Tyr (Erdmann *et al.*, 1996), while that for the common -1438 SNP is 45 percent (Cargill *et al.*, 1999). No significant associations of these rarer polymorphisms with psychiatric drug treatment response have been reported.

Parsons *et al.* (2004) reported that the presence of the A allele of -1438A/G significantly increased promoter activity in a reporter gene assay compared to the G allele, although whether this translates to effects in the brain *in vivo* is unclear. A *post-mortem* brain study found that the C allele of 102T/C was associated with lower mRNA and lower protein expression than the T allele (Poleskaya and Sokolov, 2002), while a study by Bray *et al.* (2004) using the highly accurate quantitative allele-specific primer extension assay found no evidence for differences in mRNA expression between the 102T and C allelic forms of the 5-HT<sub>2A</sub> receptor mRNA in *post-mortem* brain tissue derived from frontal, parietal or temporal cortex of the individuals heterozygous for this polymorphism. These findings would be consistent with the functionality residing with the -1438 SNP and apparent effects of the 102T/C site due to linkage disequilibrium with this site.

Myers *et al.* (2007) reported that variation in gene expression was associated with the -1438A/G and -783A/G polymorphisms, the minor G allele at -783 when expressed with the G allele at -1438 significantly decreased promoter activity of the gene. In the same study, mRNA expression in human fibroblast cell lines confirmed that -783A/G polymorphism significantly

modified the effects of the  $-1438A/G$  SNP. Despite the assumption that the promoter polymorphisms are primarily responsible for functional differences in  $5-HT_{2A}$  receptor expression, there is some evidence that the  $102C/T$  site SNPs have an influence. DNA methylation can be responsible for expression differences between alleles; Polesskaya *et al.* (2006) studied methylation in two CpG sites, which are specific to allele C ( $102C/T$  polymorphism), and found that levels of methylation in the promoter correlated significantly with expression of the  $5-HT_{2A}$  receptor.

Polymorphisms of the  $5-HT_{2A}$  receptor gene have been associated with many psychiatric diagnoses, including psychoses, affective disorders and anxiety disorders, although these genetic association studies with disease report generally weak and conflicting results. Meta-analysis of the many studies in schizophrenia suggested an association of the  $102C/T$  SNP (Abdolmaleky *et al.*, 2004), not confirmed in a later study (Li *et al.*, 2006a); there was also no significant effect in meta-analyses of association with suicidal behavior (Anguelova *et al.*, 2003; Li *et al.*, 2006a), despite positive findings in each case. However, in addition to the many association studies with psychiatric diagnoses, there are strong indications of association with response to treatment, particularly relating to antidepressants and antipsychotics (as reviewed by Lane *et al.*, 2005; Serretti *et al.*, 2007).

### Pharmacogenetics

Some examples of these associations provide an indication of the difficulties associated with drawing definitive conclusions regarding the value of these pharmacogenetic studies. Lane *et al.* (2002) indicated that the  $5-HT_{2A}$  receptor  $102C/C$  genotype is related to better clinical response to risperidone in Chinese patients. However, Arranz *et al.* (1998) showed that the  $102C/C$  genotype is more frequent among clozapine non-responders than responders in Europeans. The fact that the clozapine study was performed with previously treatment-resistant patients may contribute to such discrepancies in results.

Joobar *et al.* (1999) suggest that the  $102C/C$  genotype tended to be more frequent in patients with schizophrenia with poor long-term outcome and poor response to typical antipsychotic drugs. This difference was significant in men but not in women. In addition, the age at first contact with psychiatric care was significantly lower in the patients with schizophrenia with genotype  $C/C$  than in patients with genotype  $TT$ .

In a large prospective study of patients with major depressive disorder who were treated with citalopram, McMahon *et al.* (2006) showed that participants who were

homozygous for the  $-1438A/G$  allele had an 18 percent reduction in absolute risk of having no response to treatment, compared with those homozygous for the  $G$  allele. However, there may be racial differences in outcomes of antidepressant treatment. Choi *et al.* (2005) reported a better response to citalopram treatment in Korean patients with major depressive disorder who had the  $G/G$  genotype.

There also have been studies trying to identify genetic markers for intolerance to antidepressant medication in the light of  $5-HT_{2A}$  functionality. Murphy *et al.* (2003) reported that discontinuation of paroxetine treatment in elderly patients with major depression due to side effects was strongly associated with the  $102C/T$  polymorphism. There have been several studies investigating possible associations with drug-induced weight gain, although no consistently replicated evidence supports a role for  $5-HT_{2A}$  receptor polymorphisms in this important side effect associated with several antipsychotic drugs.

Some studies concentrated on investigating the association of  $5-HT_{2A}$  receptor gene polymorphisms with tardive dyskinesia as a side effect of long-term antipsychotic treatment. A recent study by Boke *et al.* (2007) showed that the  $-1438A/A$  genotype is a risk factor for developing tardive dyskinesia in Turkish schizophrenia patients. A large, multicenter study by Lerer *et al.* (2005) found that the  $102C/T$  genotype was significantly associated with tardive dyskinesia in older (median age 47) but not younger patients, and in patients with non-orofacial but not orofacial tardive dyskinesia. An earlier study by Segman *et al.* (2001) also suggested that the  $5-HT_{2A}$  receptor gene is significantly associated with susceptibility to tardive dyskinesia, with the  $102C/C$  and the  $-1438G/G$  genotypes being associated with significantly higher abnormal involuntary movement scores. Association of the  $102C/T$  genotype with tardive dyskinesia was also shown in the study by Tan *et al.* (2001), with a significant difference remaining after adjustment for age and antipsychotic dosage.

However, there are some studies with negative association results. Thus, Basile *et al.* (2001) studied three polymorphisms in the  $5-HT_{2A}$  receptor gene without demonstrating any association with the development of tardive dyskinesia, and a more recent study came to the same conclusion with the  $102C/T$  allele (Güzey *et al.*, 2007). Racial differences, as well as differences between the types of disorder (orofacial or limb/trunk dyskinesias), may account for some of the differences regarding what is at most a weak pharmacogenetic effect.

### $5-HT_{2C}$ receptor

Like the  $5-HT_{2A}$  receptor, the  $5-HT_{2C}$  receptor is a primarily postsynaptic excitatory G-protein-coupled receptor mediating many aspects of  $5-HT$  function.  $5-HT_{2C}$

receptors have their highest density in the choroid plexus, but are found in basal ganglia and limbic regions of the brain, where they may also be involved in the effects of some of antipsychotic and antidepressant drugs. These receptors appear to inhibit dopaminergic activity, influencing motor function (Alex and Pehek, 2007), and are implicated in the motor effect of antipsychotic drugs (Reavill *et al.*, 1999) and the emergence of dyskinesias (Eberle-Wang *et al.*, 1996).

5-HT<sub>2C</sub> receptors also have effects on food intake and other endocrine-influenced behaviors, due to their presence in the hypothalamus. Thus, transgenic mice without a functional 5-HT<sub>2C</sub> receptor gene demonstrate late-onset obesity (Tecott *et al.*, 1995). These 5-HT<sub>2C</sub> knockout mice are hyperphagic and exhibit metabolic hormone changes, including the development of obesity, hyperleptinemia and hyperinsulinemia. Blockade of this receptor also leads to weight gain. Thus, some atypical antipsychotics and antidepressants with potent 5-HT<sub>2C</sub> antagonism may induce weight gain in susceptible individuals (Reynolds *et al.*, 2006a). However, this pharmacological action may also contribute to beneficial effects, including symptom amelioration and protection from extra-pyramidal side effects. Like 5-HT<sub>2A</sub> receptors, they are down-regulated following antidepressant treatment – an effect that, again like 5-HT<sub>2A</sub> sites, may also be brought about by antipsychotic drugs that have antagonist or inverse agonist effects at the 5-HT<sub>2C</sub> receptor.

### Genetic variability

There are several polymorphisms of the 5-HT<sub>2C</sub> receptor gene, with initial pharmacogenetic evaluation focusing on a non-synonymous coding polymorphism: Cys23Ser. Although frequent in Caucasian populations, this polymorphism is rare in Asians. Okada *et al.* (2004) showed functional differences in the activity of the expressed receptor, indicating that the Ser23 allele may be constitutively more active than Cys23. The other important 5-HT<sub>2C</sub> receptor polymorphisms studied are found within the promoter region and are present in both Caucasian and Asian populations, with minor allele frequencies of between 15 and 30 percent. Yuan *et al.* (2000) identified three single nucleotide polymorphisms (–995, now –997G/A, –759C/T and –697G/C) and a tandem repeat sequence (–1027GT), all in linkage disequilibrium. The functionality of these promoter region polymorphisms has been studied, with somewhat conflicting results. Thus, while initial studies showed the –759T and –697C alleles to demonstrate increased promoter activity, Castensson *et al.* (2005) were unable to replicate these findings fully, reporting a significant reduction in

promoter activity only in haplotypes containing –697C and –759C. More recently, it was found that in a physiologically relevant human neuroblastoma cell line, the minor –759T and –697C alleles demonstrated relatively reduced promoter activity (Hill and Reynolds, 2007). In a small study in *post-mortem* tissue reported in Reynolds *et al.* (2005a), a significant association between the –759C/T genotype and receptor density in human brain could not be identified.

### Pharmacogenetics

There are several studies of 5-HT<sub>2C</sub> polymorphisms and their association with drug response. An early study related the Cys23Ser SNP to hospitalization of patients with schizophrenia (Segman *et al.*, 1997), indicating a potential relationship to treatment response. Sodhi *et al.* (1995) found that the presence of at least one Ser23 allele was more common in patients who responded to clozapine than in those who did not, but the association of Cys23Ser polymorphism and antipsychotic drug treatment response was not confirmed in further studies (Malhotra *et al.*, 1996; Masellis *et al.*, 1998). The –759C/T polymorphism is reported to be associated with improvement of negative- and general-symptom Chinese first-episode drug-naïve patients with schizophrenia, the C allele being associated with improvement of symptoms (Reynolds *et al.*, 2005b).

Reflecting the involvement of 5-HT<sub>2C</sub> receptors in both motor function and dopaminergic control, pharmacogenetic studies have investigated association with tardive dyskinesia, the chronic consequence of treatment with several (particularly older) antipsychotic drugs. Segman *et al.* (2000) found an association of the Cys23Ser SNP with orofacial tardive dyskinesia in females, while Zhang *et al.* (2002) also found a relationship with tardive dyskinesia in Chinese patients (in whom the Cys23Ser SNP is rare) of the –697C/G promoter SNP. A recent study by Gunes *et al.* (2008) looked at the association of –997 G/A, –759 C/T, –697 G/C and Cys23Ser polymorphisms with extrapyramidal side effects in male schizophrenia patients. The 23Ser allele was associated with significantly higher frequency of extrapyramidal pathology.

The majority of pharmacogenetic studies of the 5-HT<sub>2C</sub> receptor gene have investigated drug-induced weight gain (reviewed by Reynolds *et al.*, 2005a, 2006b), reflecting the potential role of the receptor in this process, as well as the topicality of concern over iatrogenic metabolic disease. There are several functional SNPs in the 5-HT<sub>2C</sub> receptor gene which have been studied in relation to association with weight gain in patients treated with antipsychotics. The strongest evidence lies with the –759C/T polymorphism of the promoter region in the 5-HT<sub>2C</sub> receptor gene,

although this may only relate to the fact that this is the most studied of the several promoter region polymorphisms.

An association between the  $-759C/T$  polymorphism and antipsychotic drug-induced weight gain was demonstrated in a Chinese first-episode population, the T allele protecting against initial weight gain (Reynolds *et al.*, 2002). The finding was replicated in a Caucasian first-episode psychosis series following a longer-term (up to 9 months) treatment with antipsychotics (Templeman *et al.*, 2005), and has also been found in chronically-treated patients receiving olanzapine (Ellingrod *et al.*, 2005). It has been observed, too, in patients receiving clozapine (Reynolds *et al.*, 2003; Miller *et al.*, 2005), although there are some failed replications (see, for example, De Luca *et al.*, 2007). This protective effect of the T allele on antipsychotic-induced weight gain has also been shown over a short treatment period (4 weeks) in Korean patients (Ryu *et al.*, 2007), which is interesting in respect of the suggestion that the 5-HT<sub>2C</sub> receptor polymorphisms are more related to short-term effects on body weight, while other genes, including leptin, may impart greater control over the longer-term effects (Templeman *et al.*, 2005). Interactions and synergy with other genes seem likely; a haplotype study carried out on patients treated with olanzapine showed that the 102T allele of HTR2A and the 23Cys allele of HTR2C, in combination with polymorphisms in two other risk genes, were significantly associated with olanzapine-induced weight gain, with significant additive effects (Ujike *et al.*, 2008).

5-HT<sub>2C</sub> genotypes are associated with increased risk of metabolic syndrome in patients taking antipsychotics. In a cross-sectional study (Mulder *et al.*, 2007), the association of 5-HT<sub>2C</sub> receptor polymorphisms with the presence of metabolic syndrome in patients using antipsychotics was investigated. A similar study demonstrated an association with metabolic syndrome of a functional leptin promoter genotype previously found to be associated with drug-induced weight gain, but no significant effect of the  $-759C/T$  5-HT<sub>2C</sub> polymorphism (Yevtushenko *et al.*, 2008).

A haplotype study carried out on patients treated with olanzapine showed that the 102T allele of HTR2A and the 23Cys allele of HTR2C, in combination with polymorphisms of the genes for GNB3 (G protein) and the beta3 adrenoceptor, were significantly associated with olanzapine-induced weight gain, with significant additive effects (Ujike *et al.*, 2008).

### 5-HT<sub>1B</sub> and 5-HT<sub>1D</sub> receptors

These receptors share many similarities in pharmacology, and have only been clearly and definitively distinguished following the identification of their respective genes; there

is also substantial species variability which has complicated extrapolation of pharmacological findings from rat to human (Hartig *et al.*, 1996). Past studies have often failed to distinguish the two receptor subtypes, both of which act presynaptically to regulate presynaptic release of 5-HT and other neurotransmitters.

5-HT<sub>1B</sub> receptors are widely distributed in the human brain. The highest levels of mRNA expression are found in the striatum, cortex, lateral geniculate nucleus and raphe nuclei (Varnäs *et al.*, 2005). 5-HT<sub>1B</sub> receptors are located on the axon terminals of both serotonergic and non-serotonergic neurons. These receptors inhibit the release of serotonin and its biosynthesis, as well as release of other neurotransmitters, including GABA, acetylcholine, glutamate and dopamine.

The results of a number of studies suggest that reduced 5-HT<sub>1B</sub> heteroreceptor activity may increase impulsive behaviors, whereas reduced 5-HT<sub>1B</sub> autoreceptor activity may have an antidepressant-like effect (reviewed by Clark and Neumaier, 2001). Thus 5-HT<sub>1B</sub> receptors are implicated in antidepressant action and reinforcement of substance abuse. 5-HT<sub>1B</sub> receptor gene knockout mice demonstrate increased aggressive behavior and impulsivity, and are also characterized by increased susceptibility to cocaine and ethanol (Saudou *et al.*, 1994; Crabbe *et al.*, 1996; Rocha *et al.*, 1998). Over-expression of the receptor in the rat dorsal raphe nucleus has been shown to increase anxiety behavior after inescapable stress (Clark *et al.*, 2002). Further preclinical research has also shown that the 5-HT<sub>1B</sub> receptor has important modulatory effects on feeding behavior and thus body weight. In the hypophagic effect induced by 5-HT, activation of 5-HT<sub>1B</sub> receptors is required (Mancilla-Diaz *et al.*, 2005). The role of the 5-HT<sub>1B</sub> receptor in a variety of behaviors has made it the target for much neuropsychiatric and neuropharmacological research.

The same potential may be argued for the 5-HT<sub>1D</sub> site, although research here is still at an early stage. In the human brain this receptor is far less abundant than 5-HT<sub>1B</sub>, being found mainly in the ventral pallidum (Varnäs *et al.*, 2001). While the 5-HT<sub>1D</sub> receptor is likely to have a presynaptic role similar to that of the 5-HT<sub>1B</sub> site, little else about its functional role is understood.

### Genetic variability and pharmacogenetics

Investigations into the 5-HT<sub>1B</sub> receptor gene have identified a number of polymorphisms in the coding sequence and surrounding 5'- and 3'-untranslated regions (Sanders *et al.*, 2002; Duan *et al.*, 2003). These include two coding mutations, a silent 861G/C, and 371T/G, which leads to an amino acid substitution: Phe124Cys. This substitution significantly affects the pharmacological

properties of the 5-HT<sub>1B</sub> receptor, with 124Cys exhibiting higher affinity for various receptor ligands (Bruss *et al.*, 1999). Huang *et al.* (1999) described another silent 129C/T polymorphism in the coding region that was in complete linkage disequilibrium with 861C/G. The 5' SNPs appear to have functional effects on gene expression: -261T/G and -161A/T influence the binding of transcription factors (Duan *et al.*, 2003). Both of these SNPs appear to be in linkage disequilibrium with 861C/G, suggesting that the associations ascribed to the 861 SNP (see below) may be due to effects of the promoter region polymorphisms.

An allelic association of the 861 SNP with 5-HT<sub>1B</sub> binding kinetics has been reported, where the C allele was associated with decreased 5-HT<sub>1B</sub> binding (Huang *et al.*, 1999).

This SNP, first identified by Sidenberg *et al.* (1993), has attracted the most attention for a range of different hypothesis-driven associational studies, including alcoholism, suicide, eating disorders and obsessive-compulsive disorder; however, no consistent positive findings have emerged. Reports by Mundo *et al.* (2000, 2002) showed association of the 861C variant with obsessive-compulsive disorder; the absence of an association of 5-HT<sub>1B</sub> polymorphisms with schizophrenia has also been reported (Cordeiro and Vallada, 2005; Duan *et al.*, 2005). However, presence of the 861C allele has been associated with significantly lower minimum lifetime body mass indices in women with bulimia nervosa (Levitan *et al.*, 2001). Despite the apparent potential in relation to, for example, antidepressant action and weight gain, there appear to be no substantial reports relating to the psychiatric pharmacogenetics of this gene.

The 5-HT<sub>1D</sub> gene lies in a region of chromosome 1 that has been linked to anorexia; polymorphisms in the 5-HT<sub>1D</sub> receptor gene have been identified and an association with anorexia has been found and replicated (Bergen *et al.*, 2003; Brown *et al.*, 2007), although there have been studies in ADHD (Li *et al.*, 2006b) and other behavioral disorders that are negative. The functionality of the 5-HT<sub>1D</sub> SNPs has not apparently been explored. The association with anorexia would certainly indicate the potential for further investigation in association with drug-induced weight gain. However, as yet no pharmacogenetic studies have been reported.

### 5-HT<sub>3</sub> receptor

The 5-HT<sub>3</sub> receptor is unique among the 5-HT receptor family, being the only ionotropic receptor, defining a new class of excitatory ligand-gated channels. The 5-HT<sub>3</sub> receptor has five subunits (A–E) that surround an ion channel (Boess *et al.*, 1995), although to date only homomeric

(A only) or heteromeric (A and B) subunit complexes have been functionally characterized (Davies *et al.*, 1999). Within the central nervous system, 5-HT<sub>3</sub> receptors are highly expressed in the area postrema, hippocampus and amygdala, as well as in spinal cord and peripherally (Tecott *et al.*, 1993).

Fast excitatory neurotransmission mediated by 5-HT<sub>3</sub> receptors results in neurotransmitter release, especially of dopamine in mesolimbic and nigrostriatal pathways. 5-HT<sub>3</sub> receptor antagonists exhibit anti-emetic (Sugita *et al.*, 1992; Kazemi-Kjellberg *et al.*, 2001), anxiolytic (Nakagawa *et al.*, 1998) and atypical antipsychotic actions (Warburton *et al.*, 1994). Different classes of antidepressants act as non-competitive antagonists at the human 5-HT<sub>3A</sub> receptor (Eisensamer *et al.*, 2003), as well as neuroleptics (Rammes *et al.*, 2004).

Gonadal steroids might interact allosterically with the 5-HT<sub>3</sub> receptor at the receptor–membrane interface (Wetzel *et al.*, 1998). The functional antagonism of these sex hormones at the 5-HT<sub>3</sub> receptor may play a role in the development and pathophysiology of psychiatric disorders (Wetzel *et al.*, 1998).

### Genetic variability and pharmacogenetics

Several mutations of 5-HT<sub>3A</sub> gene have been described (Niesler *et al.*, 2001a). One of higher frequency (approximately 25 percent) is the 178C/T polymorphism, which encodes a Pro16Ser substitution (Niesler *et al.*, 2001b). In this study, the less common T allele was associated with an increase in the expression of the protein *in vitro* compared with the more common C allele. Association studies showed that the 178C/T polymorphism affected the susceptibility to bipolar disorder (Niesler *et al.*, 2001b) and was associated with anxiety- and aggression-related traits in women (Melke *et al.*, 2003).

Ji *et al.* (2008) reported the association of 5-HT<sub>3A</sub> receptor gene 178C/T polymorphism with the development of treatment-resistant schizophrenia. In this study, patients with the T/T genotype were receiving significantly higher neuroleptic dosage than C allele carriers. However, an associational study by Gutierrez *et al.* (2002) failed to find a difference in 178C/T genotype distributions among clozapine responders and non-responders.

Another polymorphism of the 5-HT<sub>3A</sub> receptor (1596A/G) was implicated in an association with score reductions of negative and general PANSS subscales after 8 weeks of risperidone monotherapy in Chinese drug-naïve schizophrenia patients (Gu *et al.*, 2008), although there is little evidence of or theoretical basis for consistent effects of 5-HT<sub>3</sub> subunit polymorphisms on antipsychotic drug response.

### 5-HT<sub>4</sub> receptor

5-HT<sub>4</sub> receptors are expressed in wide variety of tissues. According to Varnäs *et al.* (2003), the highest density of 5-HT<sub>4</sub> receptors is in regions of the basal ganglia, the hippocampal formation and superficial layers in the neocortex. 5-HT<sub>4</sub> receptors are also located in the periphery, including on the enteric neurons and smooth muscle cells of the gastrointestinal tract, where they are implicated in the control of motility and secretion (Crowell, 2001). 5-HT<sub>4</sub> receptors contribute to the control of dopamine secretion (Bonhomme *et al.*, 1995) and are involved in learning and memory (Letty *et al.*, 1997), providing a target for the development of drugs addressing cognitive deficits in neurodegenerative and psychiatric disorders (King *et al.*, 2008).

#### Genetic variability and pharmacogenetics

A series of eight polymorphisms of the 5-HT<sub>4</sub> receptor gene has been described (Ohtsuki *et al.*, 2002), although their functionality has yet to be explored. While associations with these polymorphisms, and/or their haplotypes, within the 5-HT<sub>4</sub> receptor gene have been observed for schizophrenia (Suzuki *et al.*, 2003), bipolar disorder (Ohtsuki *et al.*, 2002) and attention deficit hyperactivity disorder (Li *et al.*, 2006c), there have been no reports of pharmacogenetic association studies with these polymorphisms. Equally surprising is that there have been no reports of association with Alzheimer's disease or its treatment outcome, given the action of the receptor on amyloid processing (Cho and Hua, 2007).

### 5-HT<sub>6</sub> receptor

The 5-HT<sub>6</sub> receptor is a G-protein-linked receptor, and is expressed primarily in the striatum, olfactory tubercle, frontal and entorhinal cortex, nucleus accumbens, hippocampus and molecular layer of the cerebellum (Gérard *et al.*, 1997; Monsma *et al.*, 1993).

5-HT<sub>6</sub> receptors appear to regulate cholinergic and glutamatergic neuronal neurotransmission in the brain. Along with their pharmacology and anatomic distribution, this suggests possible roles for 5-HT<sub>6</sub> receptor antagonists in the treatment of learning, memory disorders, obesity and eating disorders, and, possibly, affective state and seizures (Woolley *et al.*, 2004). 5-HT<sub>6</sub> receptor antagonists improved learning consolidation in rats, improved retention in the water maze and produced a significant performance improvement in aged rats in an

operant-delayed alternation task (Meneses *et al.*, 2001). A number of other studies using different animals models have shown that 5-HT<sub>6</sub> antagonists can improve memory consolidation (King *et al.*, 2004; Mitchell and Neumaier, 2005; Mitchell *et al.*, 2007), indicating their potential in the treatment of cognitive disorders (King *et al.*, 2008; Liu and Robichaud, 2009).

This receptor exhibits high affinity for a number of tricyclic antidepressant and antipsychotic drugs, which, if this pharmacology were contributing to clinical effects, supports the view that 5-HT<sub>6</sub> receptors are a target for treating affective disorders, schizophrenia and anxiety (Monsma *et al.*, 1993; Roth *et al.*, 1994, 2004).

#### Genetic variability and pharmacogenetics

Vogt *et al.* (2000) identified six polymorphisms in the gene of the 5-HT<sub>6</sub> receptor, of which two (a silent 267C/T in exon 1 and a trinucleotide repeat polymorphism ([GCC](2/3)) in the 5'-upstream region of the gene) have been studied more extensively. An association study of these polymorphisms with susceptibility to suicide was negative (Okamura *et al.*, 2005), and a significant association between the 5-HT<sub>6</sub> receptor 267C/T polymorphism with Alzheimer's disease (Tsai *et al.*, 1999) has not been replicated (Thome *et al.*, 2001).

Pharmacogenetic studies of 267C/T polymorphism and clozapine response in schizophrenia have given contradictory results. The study by Yu *et al.* (1999) showed that patients homogeneous for 267T/T genotype had a better response to clozapine treatment; however, Masellis *et al.* (2001) did not replicate this. Absence of a positive association of -267C/T with treatment response to antidepressants in major depressive disorder was also reported by Wu *et al.* (2001).

Lee *et al.* (2005) did not find any difference in 5-HT<sub>6</sub> 267C/T genotype and allele distribution between patients with major depressive disorder and a control group; however, C/T carriers showed significantly better antidepressant treatment response than homozygote counterparts. Lane *et al.* (2004) found an association between 267C/T polymorphism and response to risperidone in acutely ill schizophrenia inpatients. T/T carriers showed less severe positive symptoms and general psychopathology compared with C allele carriers.

### 5-HT<sub>7</sub> receptor

The 5-HT<sub>7</sub> receptor is a G-protein-linked receptor, detected in high densities in layers I–III of the cortex, and several subcortical structures. The limbic system (centromedial

amygdala, anterior hippocampus, hypothalamus) is particularly well represented, indicating a potential role for the 5-HT<sub>7</sub> receptor in affective processes (Gustafson *et al.*, 1996). The 5-HT<sub>7</sub> receptor is also known to be involved in thermoregulation, circadian rhythm, learning and memory, sleep and hippocampal signaling. Hedlund and Sutcliffe (2004) hypothesized that this receptor might be involved in mood regulation, suggesting that the 5-HT<sub>7</sub> receptor is a putative target in the treatment of depression, and hence a candidate gene for antidepressant pharmacogenetics.

Several studies indicate changes in 5-HT<sub>7</sub> receptor density following antidepressant treatment. Mullins *et al.* (1999) suggested that the number of postsynaptic 5-HT<sub>7</sub> receptors in the hypothalamus is decreased in response to chronic antidepressant treatment, consistent with an earlier report by Sleight *et al.* (1995).

The 5-HT<sub>7</sub> receptor has high affinity for some atypical and typical antipsychotics (Roth *et al.*, 1994). Zhukovskaya and Neumaier (2000) reported that clozapine induced an increase in 5-HT<sub>7</sub> receptor density, as has been shown for haloperidol in rat cortex, while a significant decrease in receptor binding has been reported in schizophrenia patients compared with controls (Dean *et al.*, 2006).

### Genetic variability and pharmacogenetics

A point mutation causing amino acid substitution Pro279Leu in the 5-HT<sub>7</sub> receptor gene has been described (Pesonen *et al.*, 1998). Although the Leu279 variant is approximately three times more common among alcoholic offenders than among healthy controls, it was not significantly associated with alcoholism or impulsivity in this study.

No association between this polymorphism and obesity and eating disorders was found (Hinney *et al.*, 1999). A large case-control association study identified association of some 5-HT<sub>7</sub> SNPs with schizophrenia, notably including one in the gene promoter region. However, in a functional assay of the effect of the promoter SNP on gene expression, the authors were unable to identify an underlying functional mechanism (Ikeda *et al.*, 2006).

Despite evidence implicating 5-HT<sub>7</sub> receptors in antidepressant action, there appear to be no pharmacogenetic association studies investigating this hypothesis, or apparently assessing association with antipsychotic drug effects.

### Summary and synthesis

There is a substantial body of evidence demonstrating the involvement of genetic polymorphisms in serotonin

receptor genes in the symptom response to, and other effects of, treatment with psychiatric drugs. Many of the studies behind these findings have been strongly grounded in hypotheses that postulate association of clinical effects with known functional polymorphisms which, directly or indirectly, are likely to influence receptor density, activity and/or regulatory response. Some of the best examples here involve the -1019C/G SNP in the 5-HT<sub>1A</sub> receptor gene, in which a polymorphism influences the binding of a known transcription factor, resulting in an effect on gene expression and regulation, and consequent effects on response to treatment with drugs influencing the activity of serotonin neurons. Although this is one of the best understood processes linking a gene to therapeutics in psychiatric genetics, there are still substantial gaps in our understanding of all the mechanisms behind the effect of the SNP on 5-HT<sub>1A</sub> pharmacology. So much more remains unclear in terms of the mechanisms underlying other pharmacogenetic associations.

Much past work has inevitably investigated pharmacogenetic association with polymorphisms that have not been shown to have functional activity. Some SNPs have emerged as having functional effects on gene expression or, for missense coding region SNPs, resulting in changes in protein structure. However, many have not been investigated in this respect, or have not yielded indications of functionality, reliance being placed on their likelihood of being in linkage disequilibrium with other SNPs which influence the eventual activity of the gene product – in this case, receptor density or pharmacology.

There remains great potential in further pharmacogenetic investigation with 5-HT receptor genes. In particular, the 5-HT<sub>1B</sub> receptor, with effects on the synaptic activity of serotonin and other neurotransmitters, provides a valuable candidate gene, all the more so given the reports of functional effects of several 5-HT<sub>1B</sub> receptor gene polymorphisms. This gene, and perhaps also the 5-HT<sub>1D</sub> receptor gene, therefore provides a strong basis for hypothesis-driven association studies into, for example, drug response in the treatment of affective disorder. Drug-induced weight gain and eating disorders also provide potential studies of interest with these candidate genes. Similarly, there is a strong theoretical basis for studies on the pharmacogenetics of 5-HT<sub>4</sub> receptor polymorphisms, and particularly their role in the effects of drugs enhancing cognition in, for example, dementing disorders, schizophrenia and depression.

Of course, the pharmacogenetics of serotonin systems needs also to take into account a variety of other important genes, most notably those for the 5-HTT, tryptophan hydroxylase 2 (TPH2) and monoamine oxidase type A (MAOA), all of which demonstrate functionally important polymorphisms and which are likely to influence synaptic activity of serotonin. These are beyond the scope of the

current chapter, although the reader needs to bear in mind their potential for interaction with the serotonin receptor pharmacogenetics described here. Thus it can be seen that effects on regulatory changes in receptors, a frequent consequence of changes in synaptic neurotransmitter (and, of course, receptor ligand drugs), can be brought about by polymorphisms in these genes. This will result in effects whereby one such polymorphism may have different consequences depending on the receptor genotype present – i.e., a gene–gene interaction. Few studies have either looked for, or been powered to detect, such interactions, although they are an inevitable consequence of current pharmacogenetic findings.

## Drug addiction

## amphetamines

- human studies, 521–533
  - serotonin receptor role in addiction
    - 5-HT<sub>1A</sub>, 519–520
    - 5-HT<sub>1B</sub>, 520–521
    - 5-HT<sub>2A</sub>, 521
    - 5-HT<sub>2C</sub>, 521
    - 5-HT<sub>3</sub>, 521
    - 5-HT<sub>4</sub>, 521
    - 5-HT<sub>6</sub>, 521
  - serotonin response, 518–519
- animal models, 508–509
- cocaine
- human studies, 517–518
  - serotonin activity reduction and potentiation, 510–512
  - serotonin receptor role in addiction
    - 5-HT<sub>1A</sub>, 512–515
    - 5-HT<sub>1B</sub>, 515
    - 5-HT<sub>2A</sub>, 515–516
    - 5-HT<sub>2B</sub>, 516
    - 5-HT<sub>2C</sub>, 516
    - 5-HT<sub>3</sub>, 516–517
    - 5-HT<sub>4</sub>, 517
    - 5-HT<sub>6</sub>, 517
  - withdrawal and serotonin, 509–510
- methamphetamine
- human studies, 523
  - serotonin receptor role in addiction
    - 5-HT<sub>1A</sub>, 522
    - 5-HT<sub>2</sub>, 522
    - 5-HT<sub>3</sub>, 522–523
  - serotonin response, 522
- methylenedioxymethamphetamine
- human studies, 525
  - serotonin receptor role in addiction
    - 5-HT<sub>1A</sub>, 524
    - 5-HT<sub>1B</sub>, 524
    - 5-HT<sub>2A</sub>, 524
    - 5-HT<sub>2B</sub>, 524–525
    - 5-HT<sub>2C</sub>, 525
    - 5-HT<sub>3</sub>, 525
  - serotonin response, 523–524
- morphine and heroin
- human studies, 527–528
  - serotonin receptor role in addiction

- 5-HT<sub>1</sub>, 527
- 5-HT<sub>2</sub>, 527
- 5-HT<sub>3</sub>, 527
- 5-HT<sub>4</sub>, 527
- serotonin response, 525–527

## nicotine

- human studies, 530
- serotonin receptor role in addiction
  - 5-HT<sub>1A</sub>, 529–530
  - 5-HT<sub>2</sub>, 529
  - 5-HT<sub>3</sub>, 529
  - 5-HT<sub>4</sub>, 529
  - 5-HT<sub>6</sub>, 529
- serotonin response, 528–529
- overview, 507–508

**E**

Eating disorders, *see* Anorexia nervosa; Bulimia nervosa

Ecstasy, *see* 3,4-Methylenedioxy-methamphetamine

EEH, *see* Electroencephalography

Ejaculation, *see* Sexual behavior

Electroencephalography (EEG)

- attention deficit hyperactivity disorder, 573–574
- hippocampus
  - dorsal raphe nucleus effects, 288–289
  - median raphe nucleus effects, 282–288

Electron microscopy, *see* Axon terminal, serotonin innervation ultrastructure

## Electrophysiology

- brain serotonergic neuron studies
  - autonomic function, 156–157
  - basic characteristics, 154
  - fatigue, 159–160
  - motor activity, 157–159
  - prospects for study, 160–161
  - sleep–wake–arousal cycle, 154
  - stressor response, 154–156

## serotonin receptors

- 5-HT<sub>1A</sub>, 164–166
- 5-HT<sub>1B</sub>, 166–167
- 5-HT<sub>1D</sub>, 167
- 5-HT<sub>1E</sub>, 167
- 5-HT<sub>1F</sub>, 167
- 5-HT<sub>2A</sub>, 167–171
- 5-HT<sub>2B</sub>, 171
- 5-HT<sub>2C</sub>, 171–172
- 5-HT<sub>3</sub>, 172–174
- 5-HT<sub>4</sub>, 174
- 5-HT<sub>5</sub>, 175
- 5-HT<sub>6</sub>, 175

- 5-HT<sub>7</sub>, 175–176  
prospects for study, 176–177
- Emotion**  
definition, 367  
neuroanatomy, 367–369  
serotonergic system  
innervation of limbic system, 369–370  
modulation of emotion, 370  
neurotransmission decreasing agents, 372–373  
neurotransmission enhancing agents, 370–372  
receptor agonist studies, 374–375

**Plate 1** (A) Three-dimensional reconstruction of a cortical interneuron in layer II of the cat primary auditory cortex (green) contacted by varicose 5-HT-immunoreactive axons (red) at the surface of the soma and primary dendrites. (B) Micrograph of a coronal section in the marmoset frontal cortex containing 5-HT-immunoreactive thin and varicose axons, the latter forming a conspicuous pericellular array surrounding tightly the cell body and proximal dendrites of individual neurons. (C) Electron micrograph of an unstained post-synaptic dendrite of a cat auditory cortex interneuron (D) forming a synaptic contact with a serotonergic large varicose immunoreactive axon terminal (arrowheads). Scale bar: for (A), 8 microns; for (B), 40 microns; for (C), 1 micron.

**Plate 2** Schematic representation of a 5-HT neuron. As depicted here, a single 5-HT neuron may innervate different anatomical regions (A, B, C), including its nucleus of origin (through recurrent collaterals of its axon). In the territories of innervation, many of the 5-HT varicosities (small colored dots), distributed as rosary beads on distal branches of the axon, do not make synaptic contact (yellow dots). Others are endowed with junctional complexes, the small zone of membrane specialization, either symmetrical or asymmetrical, that is the hallmark of synapses, and make such a contact with dendritic branches (green dots), and, more rarely, dendritic spines (blue dots). Juxtapositions to cell bodies are also seen (red dots). These various configurations, schematized in the boxes, may be found within a given anatomical territory, and probably on a single axonal branch. The vesicular content of 5-HT varicosities may also vary from one anatomical region to another, and in some regions, such as the cerebellum with its mossy 5-HT fibers, or the locus coeruleus and its 5-HT varicosities filled with microvesicles and canaliculi, 5-HT terminals of a unique morphology may be found. It has been calculated that some 5-HT neurons may possess as many as hundreds of thousands of axon varicosities (Descarries *et al.*, 1990). The demonstration of the existence of asynaptic 5-HT varicosities in mammalian CNS was at the origin of the concept of diffuse (volume) transmission (for review, see Descarries and Mechawar, 2000).

**Plate 3** Human gene structures of 5-HT receptor coding sequences. This figure was generated using released data of the human genome project available on the NCBI site (<http://www.ncbi.nlm.nih.gov>) using Map Viewer interface, Gene Database and Consensus CDS Database. Builds 36.2–36.3 were used to localize the exons, except for HTR5B which was only annotated on build 35. The first column presents gene names and cytogenetic localizations. The second column schematizes the exon composition of the coding sequences and the part of the receptor encoded by each exon: open boxes, exons, bridges, splicing events, black boxes, transmembrane domains, curved lines, loops or N- or C-terminal domains. Colors indicate alternative exons and the receptor part encoded in the splice variants. The third column indicates the name and size of the gene products and splice variants (aa, amino acids). The fourth column presents size of the complete coding sequence on the human genome (b, bases; kb, kilobases).

**Plate 4** (A) Low-magnification dark-field photomicrographs showing the localization of  $\alpha_{1A}$ -adrenoceptor (A1),  $\alpha_{1B}$ -adrenoceptor (A2) and  $\alpha_{1D}$ -adrenoceptor (A3) mRNAs in the rat prefrontal cortex using *in situ* hybridization histochemistry. The sections correspond approximately to AP + 3.7 mm (Paxinos and Watson, 2005). Each receptor transcript was detected with  $^{33}\text{P}$ -labeled oligonucleotides. (B) High-magnification photomicrographs showing the presence of:  $\alpha_{1A}$ -adrenoceptor (B1),  $\alpha_{1B}$ -adrenoceptor (B2) and  $\alpha_{1D}$ -adrenoceptor (B3) mRNA ( $^{33}\text{P}$ -labeled oligonucleotides, seen as silver grains) in pyramidal cells of the prelimbic area. Pyramidal neurons were identified by the presence of vGluT1 mRNA (Dig-labeled oligonucleotides). (C) High-magnification photomicrographs showing the presence of:  $\alpha_{1A}$ -adrenoceptor (C1),  $\alpha_{1B}$ -adrenoceptor (C2) and  $\alpha_{1D}$ -adrenoceptor (C3) mRNA ( $^{33}\text{P}$ -labeled oligonucleotides, seen as silver grains) in GABAergic cells of the prelimbic area. GABAergic neurons were identified by the presence of GAD<sub>65/67</sub> mRNA (Dig-labeled oligonucleotides). Red arrowheads mark cells positive for both transcripts, blue arrowheads mark cells only positive for the receptor mRNA. For the sake of simplicity, only a few cells of each type are marked. Abbreviations: ACAAd, dorsal anterior cingulate cortex; PL, prelimbic area; ILA, infralimbic area; TT, tenia tecta; PIR, piriform cortex; AI, agranular insular cortex; MOs, secondary motor area (nomenclature from Swanson, 1998). Bar size: 1 mm (A1), 20  $\mu\text{m}$  (B1).

**Plate 5** Anatomical and functional relationship between the mPFC, the VTA, and the dorsal and median raphe nuclei (DR/MnR). Pyramidal neurons of the mPFC project directly to mesocortical (but not mesoaccumbal) dopamine (DA) neurons, closing a mPFC-VTA circuit. GABAergic cells in the VTA project to mPFC and limbic areas as well. The mPFC may also modulate the activity of VTA neurons indirectly, through the basal ganglia circuit (e.g., mPFC nucleus accumbens ventral pallidum (VP) pathway) or through afferents to the LDT/PPTg. Likewise, the mPFC is reciprocally connected with the DR/MnR. Pyramidal neurons of the mPFC project to raphe 5-HT and GABA neurons and modulate their activity. In turn, 5-HT neurons modulate the activity of pyramidal cells in the mPFC through various receptors, in particular 5-HT<sub>1A</sub> and 5-HT<sub>2A</sub> receptors, which are expressed by pyramidal and GABAergic neurons. The pharmacological activation of these receptors in the mPFC has been shown to modulate 5-HT neuron activity and terminal 5-HT release via descending afferents to the midbrain. In addition, to the mPFC, 5-HT<sub>1A</sub> receptors are densely expressed in the DR/MnR (autoreceptors) and in areas projecting to the mPFC, such as the hippocampal formation. Direct 5-HT afferents to the VTA may also be involved in the control of DA neurons by other 5-HT receptors, notably the 5-HT<sub>2C</sub> subtype, present in GABAergic neurons of the VTA. Abbreviations: Glu, glutamate; Pyr, pyramidal neuron; Ach, acetylcholine; N. Accumbens, nucleus accumbens; iGluR, Ionotropic glutamate receptor; KA, kainic acid.

**Plate 6** 5-HT neurons are chemosensitive *in vivo* and are closely associated with large blood vessels. (A) A subset of neurons in the raphe pallidus express c-Fos when exposed to hypercapnia (right panel). Some of these neurons are immunoreactive for 5-HT (left panel). Open arrow: 5-HT neuron that does not express c-Fos. Closed arrows: 5-HT neuron that is immunoreactive for c-Fos. Asterisk: C-Fos positive neuron that does not express 5-HT. Scale bar: 20  $\mu$ m. (B) Medullary raphe neurons are closely related to the basilar artery and its large penetrating branches. Shown is a transverse section of the medulla. 5-HT neurons are immunostained with an antibody against tryptophan hydroxylase (green). Blood vessels are filled with fluorescent albumin (red). Scale bar: 200  $\mu$ m. (C). Shown is a neuron in the medullary raphe that was filled with biocytin (green) after patch-clamp recording. This neuron was stimulated by acidosis and was immunoreactive for tryptophan hydroxylase (blue). It had processes that were closely associated with large blood vessels (red). (C)

**Plate 8** Sudden infant death syndrome (SIDS) is associated with abnormalities of the 5-HT system. (A) Developmental changes in the human medullary raphe nuclei at the mid- and rostral medullary levels. Blue dots, raphe 5-HT neurons; green dots, extra-raphe 5-HT neurons; red dots, 5-HT neurons on the ventral surface including the arcuate nucleus. Scale bar: 1 cm. (B) Tritiated LSD binding to 5-HT receptors is decreased in the raphe obscurus of infants that have died of SIDS. The scatter plot shows  $^3\text{H}$ -LSD binding as measured with quantitative tissue receptor autoradiography in the raphe obscurus relative to postconceptional age for SIDS cases (solid triangles) compared to control infants that died of acute causes (open circles) or diseases that caused chronic hypoxia (closed circles). (C) Comparison of distribution of 5-HT neurons of a SIDS case and a control case. In the midline raphe of the SIDS infant there is an increased number of 5-HT neurons. (A) Reproduced with permission from Elsevier: *Autonomic Neuroscience* (Kinney, 2007) 132: 81–102, ©2007. (B) Reproduced with permission from Lippincott, Williams & Wilkins, Inc.: *Journal of Neuropathology and Experimental Neurology* (Panigrahy *et al.*, 2000) 59: 377–87. (C) Reproduced with permission from the American Medical Association: *Journal of the American Medical Association* (Paterson *et al.*, 2006) 296: 2124–2132 ©2006.

**Plate 9** Parkinson's disease involves the 5-HT system early and many patients have abnormalities of breathing and chemoreception. (A) Braak staging of neurodegeneration in idiopathic PD. Note that 'gain-setting nuclei', which includes the raphe nuclei, are involved earlier in the disease process than dopaminergic neurons of the substantia nigra. (B) Progression of disease in PD begins in the lower brainstem and progresses rostrally. (A) Reproduced with permission from Springer: *Cell Tissue Research* (Braak *et al.*, 2004) 318: 121–34, ©2004.

**Plate 10** Diagrammatic illustration of the topographical distribution of serotonergic neurons projecting to functionally related forebrain and hindbrain targets in the rat brain. Serotonergic neurons projecting to the caudate putamen and substantia nigra (blue) are located predominantly in the rostral part of the DR and are concentrated within clusters in the DRN 'core' and DRV 'ellipse' regions of the mid-rostrocaudal parts of the DR. Serotonergic neurons projecting to brain structures implicated in the regulation of anxious states and anxiety-related behaviors (yellow) are concentrated in the mid-rostrocaudal DRN 'shell' region and caudal DR. Populations of serotonergic neurons in the DRVL/VLPAG region (red) project to the DPAG and RVLM and have been implicated in the inhibition of panic-like responses. Serotonergic neurons in the DRI (green) have projections to the prefrontal cortex, hippocampus, and midline thalamus, are thought to be activated by peripheral immune activation, and may play an important role in coping and resilience. Abbreviations: Acb, nucleus accumbens; BL, basolateral amygdala; BNST, bed nucleus of the stria terminalis; CE, central nucleus of the amygdala; CP, caudate putamen; DA, dorsal hypothalamic area; dHPC, dorsal hippocampus; DRN, dorsal raphe nucleus, dorsal part; DRI, dorsal raphe nucleus, interfascicular part; DRV, dorsal raphe nucleus, ventral part; DRVL/VLPAG, dorsal raphe nucleus, ventrolateral part/ventrolateral periaqueductal gray; DPAG, dorsal periaqueductal gray; LC, locus coeruleus; LPB, lateral parabrachial nucleus; mPFC, medial prefrontal cortex; RVLM, rostral ventrolateral medulla; SN, substantia nigra; vHPC, ventral hippocampus. Scale bar, 500  $\mu$ m. Reproduced from *Stress: The Biology of Stress*, 12 January 2005, Christopher A. Lowry, Philip L. Johnson, Anders Hay-Schmidt *et al.* 'Modulation of anxiety circuits by serotonergic systems' 8:4, pp. 233–246, reprinted by permission of Taylor & Francis Ltd, <http://www.tandf.co.uk/journals>.

**Plate 11** Illustrations and photomicrographs showing retrogradely labeled neurons in the dorsal raphe nucleus following injections of Cholera Toxin B-subunit (CTb) into the basolateral nucleus of the amygdala. (A) Illustrations of the distribution of basolateral amygdala-projecting serotonergic (black squares) and non-serotonergic (white squares) neurons within subdivisions of the dorsal raphe nucleus. Retrogradely labeled neurons are concentrated in the mid-rostrocaudal dorsal raphe nucleus (gray shaded areas at  $-8.00$  mm and  $-8.18$  mm Bregma) (Paxinos and Watson, 1998). Most but not all BL-projecting neurons in the dorsal raphe nucleus are serotonergic. (B) Photomicrograph illustrating the CTb injection site restricted to the BLA and BMA. (C) Double-labeled immunofluorescence photomicrograph showing the mid-rostrocaudal dorsal raphe nucleus (corresponding to  $-8.18$  mm Bregma) illustration in (A). White box in (C) indicates region shown at higher magnification in (D). White box in (D) indicates region shown at higher magnification in E, F and G. Tryptophan hydroxylase-immunoreactive (TrpOH-ir; serotonergic) neurons appear red (E), while CTb-ir (BL-projecting) neuron appears green (F). Double TrpOH/CTb immunofluorescent neuron appears yellow. Abbreviations: BLA, basolateral nucleus of the amygdala, anterior part; BLP, basolateral nucleus of the amygdala, posterior part; BLV, basolateral nucleus of the amygdala, ventral part; BMA, basomedial nucleus of the amygdala, anterior part; DRN, dorsal raphe nucleus, dorsal part; DRV, dorsal raphe nucleus, ventral part; ec, external capsule; lab, longitudinal association bundle. Scale bar:  $448\mu\text{m}$  (A);  $500\mu\text{m}$  (B);  $100\mu\text{m}$  (C);  $50\mu\text{m}$  (D),  $25\mu\text{m}$  (E, F, G).

**Plate 12** A dorsal view of an *Aplysia* showing the animal's respiratory organ: the gill. When the siphon is stimulated by the application of a tactile stimulus, the siphon is contracted and the gill is withdrawn under the mantle shelf (right, top). This withdrawal reflex is a protection reflex that undergoes habituation (right, middle) when the stimulation is repeated, or which may show sensitization after a noxious stimulus is applied to another part of the body (e.g., a hurt on the tail; right bottom). Dishabituation (not-illustrated) is a term used to describe what happens once habituation has been established and a noxious stimulus is applied to another part of the body; in this case, the habituation of the withdrawal reflex is relieved. The scattered line indicates the limits of the non-retracted gill, as shown on the *Aplysia*, left.

**Plate 13** Alterations of the serotonergic system/synapses can be achieved by different methods. Depletion may be obtained by irreversible damage to the neurons by the means of intracerebroventricular 5,7-dihydroxytryptamine (5,7-DHT), which is taken up by the serotonin transporter (a), by pCPA-induced blockade of the 5-HT-synthesizing enzyme, tryptophan hydroxylase (b), by placing subjects under tryptophan-depleted food regimens (c), or by pCA- or MDMA-induced alterations of 5-HT terminals (d). Increased 5-HT functions can be obtained by acute pCA-induced release of 5-HT (e), by blockade of the serotonin transporter (SERT; f), or the administration of tryptophan-enriched food regimens (g). Another way to interfere with serotonergic function is based on the administration of ligands that may more or less selectively block (antagonists) or activate (agonists) the receptors (h), which are of the metabotropic (5-HT<sub>1</sub>, 5-HT<sub>2</sub>, 5-HT<sub>4</sub>, 5-HT<sub>7</sub>) or inotropic (5-HT<sub>3</sub>) type; depending on the species, the auto-receptor is of the 5-HT<sub>1B</sub> or 5-HT<sub>1D</sub> subtype. As regards the receptors, it is also possible to genetically delete them in mice (i). In general, (d), (g) and (h) can be used both in experimental animals and human subjects, but all other approaches are restricted to animal models (most often to mice, rats, monkeys, less frequently to guinea pigs, as concerns the study of CNS functions).

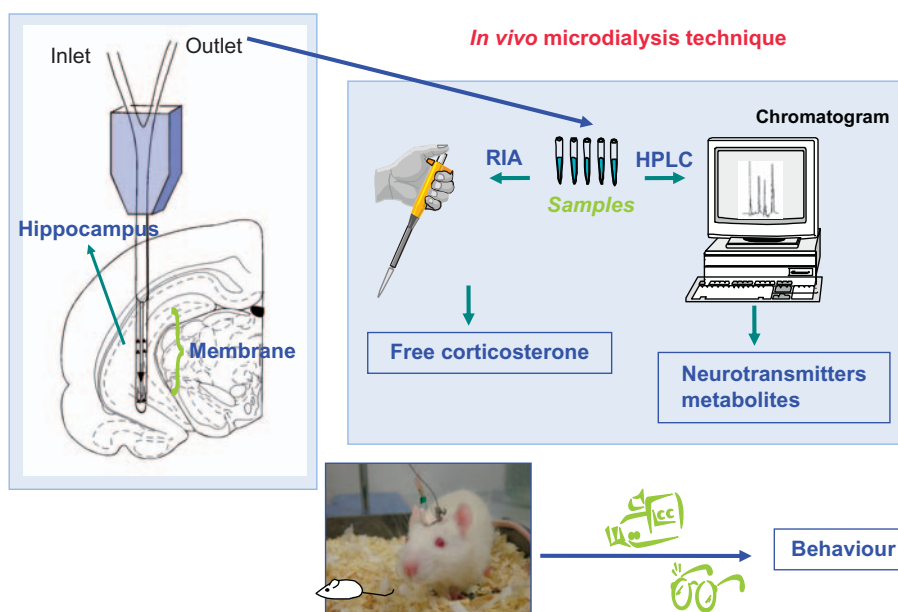

**Plate 14** Simplified schematic drawing of 5-HT action in the periphery.

**Plate 15** Simplified schematic drawing of the 5-HT descending system in the spinal cord.

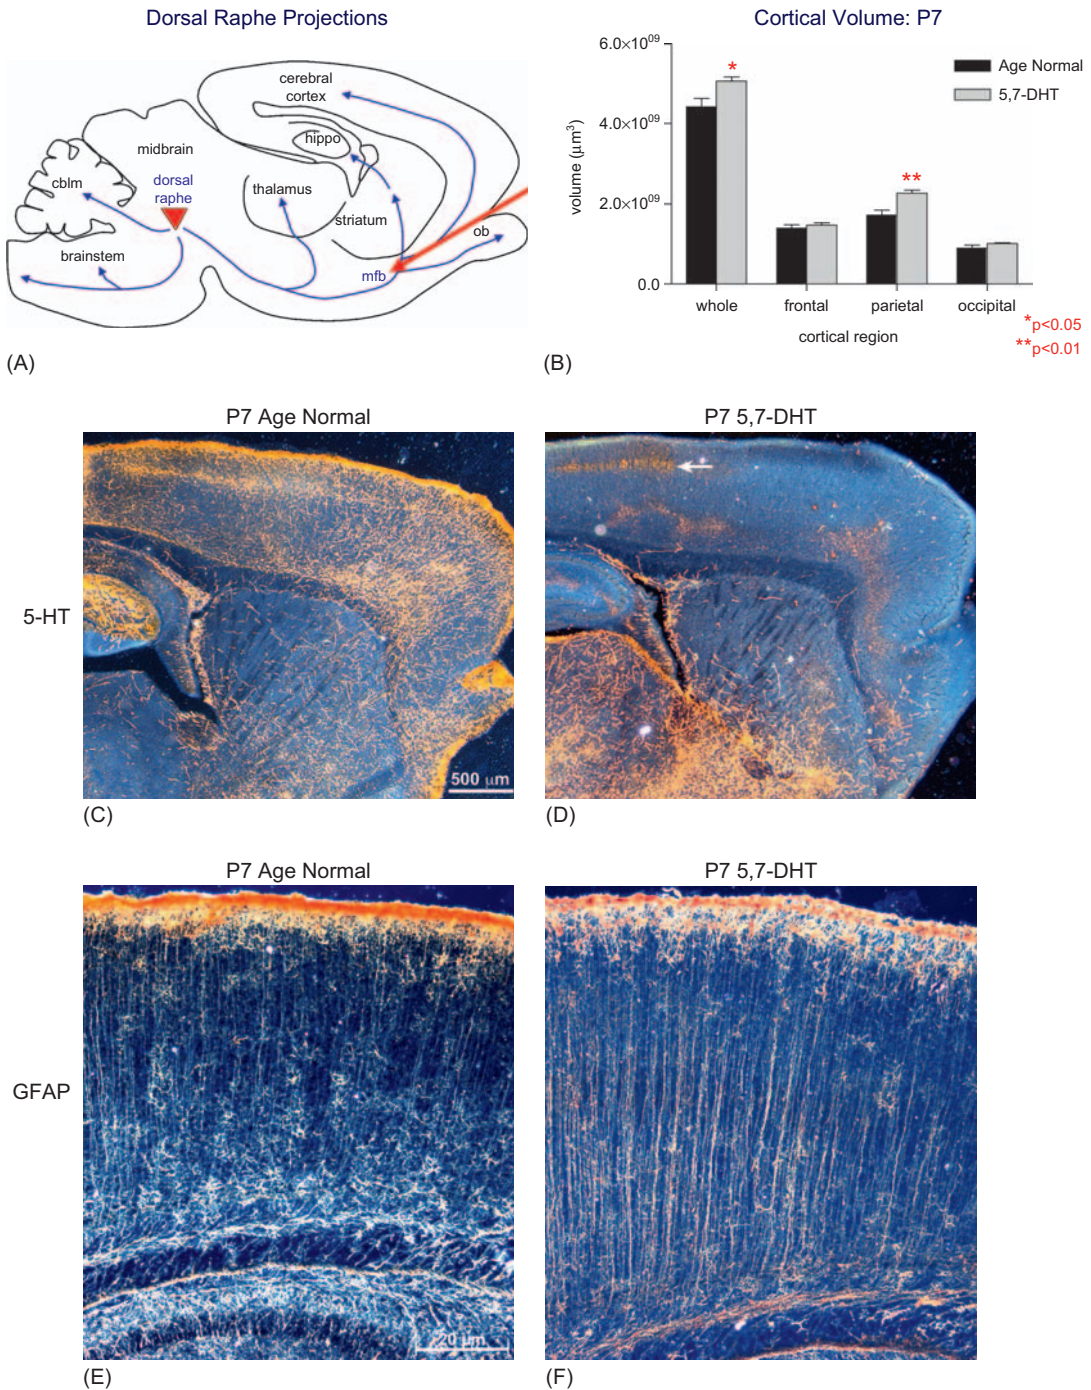

**Plate 16** Schematic overview of the microdialysis technique as applied in our laboratories. A microdialysis probe is inserted through a guide cannula (not depicted, implanted 7–10 days earlier; the dialysis probe depicted is the CMA12 of CMA Microdialysis/AB, Stockholm, Sweden) exposing the dialysis membrane to the brain tissue of interest (shown here is the hippocampus). The microdialysis probe is perfused with Ringer solution via a microinfusion pump (not depicted). Drugs can be delivered to the target tissue by inclusion in the perfusion fluid (so-called retrodialysis or reverse dialysis). Animals are connected to a swivel system and counterbalance arm via a little peg anchored to the dental cement on their skull (see picture) giving them the opportunity to move freely in all directions. Samples are collected using automated microsamplers, and are subsequently used to measure various molecules in the dialysates – e.g., neurotransmitters and their metabolites – by high-pressure liquid chromatography (HPLC) with electrochemical detection or free corticosterone levels via radioimmunoassay (RIA). Behavior of the rats or mice is continuously scored during the microdialysis experiments by visual observation or is subsequently analyzed from videotape. Experiments are performed under baseline conditions, and during and following stressful challenges or behavioral testing. Note that this method allows the simultaneous collection of information on the status and responsivity of various neurotransmitter systems in the brain, on the activity of the HPA axis and on behavior, providing strong, integrative data and representing a clear example of refinement and reduction (Russell and Burch, 1959) in animal research.

**Plate 17** Inverse Correlation of 5D-ASC Global Scale scores and [ $^{18}\text{F}$ ]altanserin apparent distribution volume [ $\text{DV}'$ ]. Results of a voxel based correlation analysis (? 5D-ASC global vs  $\Delta\text{DV}'$ , threshold  $P < 0.005$ , uncorrected) using Statistical Parametric Mapping (SPM2) (Hasler, Quednow, Vollenweider, unpublished data).

**Plate 18** Comparison of the R-( $\alpha$ )- isomer of a potent difuranobenzene phenethylamine type hallucinogen (A) with S-( $\alpha$ )- $\alpha$ -methylserotonin (B). Although the stereochemistry at the carbon bearing the  $\alpha$ -methyl is reversed for the phenethylamines and the tryptamines, the lengths of the ligands, differing by about 0.5 Ångstroms (C), could be the underlying reason for this reversal. The bicyclic aromatic indole system of the tryptamines is longer than the phenyl ring of the phenethylamines, and thus when the side-chain is extended, the tryptamines will occupy a larger space in the receptor. Because the receptor evolved to accept serotonin, a tryptamine, the perspective must be one that the phenethylamines somehow adapt themselves to a binding site that prefers tryptamines.

**Plate 19** 5,7-DHT mouse model. (A) Schematic drawing of a parasagittal section through a P7 mouse brain showing the location of the serotonergic neurons in the dorsal raphe and the projections from the raphe to multiple brain regions. Serotonergic axons innervate the hippocampus (hippo) and cerebral cortex via the medial fore-brain bundle (mfb). The red arrow indicates the path of the 5,7-DHT injections. cblm, cerebellum; ob, olfactory bulb. (B) The volume of the whole cerebral cortex and parietal regions was greater in 5,7-DHT lesioned mice than in Age Normal controls. (C, D) Dark field photomicrographs show the distribution of serotonergic axons (5-HT) in parasagittal sections of (C) P7 Age Normal and (D) 5,7-DHT lesioned mouse brains. In lesioned mice, there are many fewer afferent serotonergic axons in the cortex and the hippocampus. However, some serotonin remains in thalamocortical terminals due to their transient expression of the serotonin transporter (white arrow). (E, F) The pattern of immunostaining for glial fibrillary acetic protein (GFAP) is shown in the dark field photomicrographs of the cortex in (E) Age Normal and (F) 5,7-DHT lesioned mouse brains. At P7, many of the radial glial fibers remain present, and their density appears higher in the lesioned mice.

**Plate 20** Modulation of aggressive behaviors by microinjections of 5HT<sub>1A</sub>, 5-HT<sub>1B</sub>, and 5-HT<sub>2A/2C</sub> receptor agonists. Text boxes show that local injection of 5-HT<sub>1A</sub> receptor (1A), 5-HT<sub>1B</sub> receptor (1B), or 5-HT<sub>2A/2C</sub> receptor (2A/2C) agonist increases (↑), decreases (↓) or has no effect ('0') on territorial, escalated, maternal, and defensive aggressive behaviors. Serotonergic neurons originated from raphe nuclei project to several brain areas.
